The Cyanokit contains two 2.5-g vials of hydroxocobalamin. Hydroxocobalamin binds directly with CN to rapidly form nontoxic cyanocobalamin (vitamin B_{12}), which is subsequently excreted in the urine. In addition, hydroxocobalamin has been shown to raise blood pressure, potentially advantageous in treatment of the patient with CV collapse (8). The main side effect of hydroxocobalamin is a clinically insignificant reddish-brown skin discoloration that resolves spontaneously. It also causes red discoloration of the urine and blood, potentially interfering with some colorimetric laboratory studies so if there is time, tubes of blood should be gathered for subsequent laboratory analysis prior to administration of hydroxocobalamin. The adult dose is 5 g of hydroxocobalamin reconstituted in 100 mL 0.9% sodium chloride and given intravenously over 15 minutes; the pediatric dose is 70 mg/kg. A second dose may be repeated over 15 minutes to 2 hours for severe poisoning. Metabolism of cyanogenic glycosides or aliphatic nitrile compounds to CN cause prolonged poisoning, requiring multiple antidote doses.

The Cyanide Antidote Kit, in use for decades in the United States, has been discontinued but a kit containing sodium nitrite 3% solution and sodium thiosulfate 25% solution is still available. The adult dose of sodium nitrite is one 10-mL ampule (300 mg) of the 3% solution administered intravenously. The pediatric dose ranges from 0.12 to 0.33 mL/kg (3.6 to 9.9 mg/kg). **Sodium nitrite is a potent vasodilator; rapid administration may result in severe hypotension,** which can be avoided by giving the sodium nitrite in 50 to 100 mL of D_5W slowly intravenously over 5 minutes. Start the

infusion slowly, with frequent blood pressure monitoring, and then increase to the most rapid infusion without causing hypotension. Sodium thiosulfate 25% solution is also administered intravenously and is supplied in a 50-mL vial (Adult dose: One entire vial. Pediatric dose: 1.65 mL/kg up to 50-mL maximum). A second half dose of sodium nitrite and sodium thiosulfate may be given after 30 minutes if there is an incomplete clinical response. Repeated doses or a continuous infusion (1 g/hr) of sodium thiosulfate (without further sodium nitrite) should be considered if there is ongoing metabolism to CN following ingestion of a cyanogenic compound.

In addition to its vasodilatory effects, sodium nitrite induces formation of methemoglobin, which binds CN to form cyanohemoglobin as part of the detoxification process. Methemoglobin levels should be monitored, especially if multiple doses of sodium nitrite are required, and should be kept to $<30\%$ of total hemoglobin. When oxygen transport is already compromised, as in a smoke-inhalation patient with concomitant carbon monoxide poisoning, this induction of methemoglobinemia further impairs cellular hypoxia (see Chapter 319). This situation can be avoided by using hydroxocobalamin, but if it is not available, a reasonable approach in the critically ill smoke-inhalation patient with suspected CO and CN poisoning, is to administer only the sodium thiosulfate without the sodium nitrite. Sodium thiosulfate indirectly metabolizes CN by catalyzing the body's own conversion of CN to sodium thiocyanate.

Because activated charcoal has decreased mortality in experimental CN poisoning (9) and 1 g may bind as much as 35 mg of CN, consider giving 1 g/kg activated charcoal in patients who have ingested CN.

Extracorporeal elimination procedures such as hemodialysis and hemoperfusion have no place in the treatment of acute CN poisoning. Hyperbaric oxygen therapy has not lowered CN concentrations in fire victims with concomitant carbon monoxide poisoning (10).

CRITICAL INTERVENTIONS

- Suspect CN poisoning in patients with rapid development of unexplained coma, seizures, elevated plasma lactate, elevated anion gap metabolic acidosis, and intractable hypotension.
- Suspect CN poisoning in comatose and critically ill patients with smoke inhalation.
- Administer hydroxocobalamin intravenously (adult dose: 5 g) to comatose or persistently acidotic or seizing patients with possible CN exposure.

DISPOSITION

Asymptomatic CN-exposed patients should be observed in a controlled setting for 4 to 6 hours. Following ingestion of cyanogenic compounds or foods, the observation period should be extended to 12 hours. Mildly symptomatic patients can be observed in the ED until symptoms resolve. Those requiring antidote administration should be admitted to an intensive care unit for a minimum of 24 hours or until all symptoms have resolved.

Survivors of acute CN poisoning have developed parkinsonian-like states or more subtle neuropsychiatric deficits (11). Outpatient follow-up should be arranged for patients with significant acute toxicity to screen for these sequelae.

If transfer is necessary, the most rapid means available should be used with personnel who can initiate intravenous access, perform endotracheal intubation and mechanical ventilation, and administer specific antidotes, sodium bicarbonate, anticonvulsants, and anti-arrhythmic medications.

Common Pitfalls

- Failure to stock an in-date CN antidote in the ED or other readily available location.
- Failure to consider the diagnosis of CN poisoning in patients with smoke inhalation, sudden-onset coma, CV collapse, or lactic acidosis of unknown etiology.
- Waiting for laboratory confirmation before antidote administration in unstable patients.

- Using sodium nitrite with concomitant carbon monoxide poisoning in a smoke-inhalation patient.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Alan Hall, to the content of this chapter.

CHAPTER 330

Fluoride and Hydrofluoric Acid

Kennon Heard

Fluoride, the most electronegative anion, binds strongly to divalent serum cations such as calcium and magnesium. In the body, this precipitates as fluoride salts, resulting in hypocalcemia and hypomagnesemia. Fluoride inactivates enzymes required for cellular metabolism and may activate intracellular second messengers. Fluoride also interferes with Na+/K+-ATPase and activates calcium-dependent potassium channels in cell membranes, causing potassium to enter into the extracellular space, with potential hyperkalemia. Hypocalcemia, hypomagnesemia, and hyperkalemia contribute to cardiac dysrhythmias. Hypocalcemia also inhibits calcium-dependent clotting factors and can cause coagulopathy.

Although fluoride is found in many household dental products (e.g., toothpaste), exposure to these products rarely results in serious effects (1). However, ingestion of prescription dental products may result in serious toxicity. Sodium fluoride has been used as a pesticide. Ammonium fluoride and ammonium bifluoride are been used as wheel cleaners, and have caused several cases of severe accidental poisoning.

As a relatively weak acid (pKa = 3.8), hydrofluoric acid (HF) damages tissue primarily through the strong electronegative effect of the fluoride ion. HF is found in products used for glass etching, grout cleaners, and silicon chip manufacturing. It is also used in household and commercial rust removal products. The effect is determined by the concentration of HF in the product. Low-

concentration exposures may not cause an initial caustic injury but can still cause significant tissue damage and pain. High-concentration exposures found in commercial products may cause life-threatening systemic poisoning and classic caustic injury.

CLINICAL PRESENTATION

Dermal HF exposures are the most commonly encountered fluoride exposure in the emergency department (ED). Exposure to other fluoride cleaning products (e.g., ammonium bifluoride) may cause similar effects. The major manifestation of these exposures is pain. At low concentrations (<20% HF), symptoms may be delayed more than 24 hours (2). With lower-concentration exposures, dermal findings range from normal appearing skin to full-thickness burns. In one series of low-concentration exposures, just over half of the patients had erythema and swelling, 5% developed blisters, but 23% had normal appearing skin (2). Burns from high concentrations (>50% HF) may appear similar to other caustic injuries. Exposure of more than 1% of the total body surface area (TBSA) to a 50% HF product may result in systemic poisoning. Ocular exposures to low-concentration products may result in eye pain and corneal injury, and animal models suggest that exposure to concentrations >20% will cause immediate corneal edema and opacification.

Patients with HF ingestions may have deceptively minimal or no findings suggestive of caustic exposure. Fatal fluoride intoxication following ingestion has been reported without significant gastrointestinal (GI) symptoms (3). When present, GI symptoms include abdominal pain, vomiting, and hematemesis (3). Effects after HF inhalation may range from mild pulmonary irritation to hemorrhagic pulmonary edema and delayed multisystem organ failure. Systemic absorption of fluoride may occur after inhalational exposure. Manifestations of systemic fluoride poisoning include headache, paresthesias, visual complaints, and signs of hypocalcemia such as carpal-pedal spasm, positive Chvostek sign and Trousseau sign, hyperreflexia, tetany, and prolongation of the QT interval on the electrocardiogram. Hypocalcemia is often severe

(serum calcium level <5 mg/dL). Metabolic acidosis, hypomagnesemia, hyperkalemia, and coagulopathy can also occur. Coma, seizures, shock, dysrhythmias, and death may occur in severe cases. Lethal dysrhythmias include refractory ventricular tachycardia and ventricular fibrillation.

DIFFERENTIAL DIAGNOSIS

HF acid exposure should be strongly considered when a patient presents following a dermal exposure with severe pain and minimal dermal findings. Other diseases with similar findings would include other chemical burns, Raynaud syndrome, local ischemia, or sensory neuropathy. Systemic fluoride poisoning should be considered for the patient who presents with cardiovascular (CV) instability and hypocalcemia. Other potential causes of this presentation would include acute hypoparathyroidism, hyperphosphatemia or poisoning from sodium ethylenediaminetetraacetic acid.

ED EVALUATION

Important factors in the history include the route of exposure, the strength and concentration of the product involved, the use of protective equipment, and whether decontamination was performed. Signs and symptoms and their time of onset with respect to exposure should be noted. The physical examination should initially focus on the site of exposure. Patients with facial burns should have conjunctival pH determined and a full eye examination performed after any needed irrigation. Patients with limited (<5% body surface area) dermal exposures to low (<10%) concentration HF products do not require any laboratory testing or monitoring. Patients with more extensive dermal exposures, dermal exposure to higher (>20%) concentration products, or ingestion of HF products should have an electrocardiogram and serum calcium determinations. Cardiac monitoring for prolongation of the QT interval is recommended, although the diagnostic accuracy of the QT interval for predicting toxicity is not known.

Patients with hypocalcemia should have a complete blood count, serum electrolytes, magnesium, blood urea nitrogen, and creatinine. Chest radiographs are indicated for symptomatic patients with inhalational exposure.

KEY TESTING

- Rapidly determine serum calcium in patients with large- or high-concentration dermal exposures and in patients who have ingested nondental fluoride products
- Cardiac monitoring for hypocalcemia, QT prolongation, and potential dysrhythmias
- Serum magnesium

ED MANAGEMENT

The first step with dermal exposure is immediate (ideally at the scene of exposure) irrigation with water. In a series of more than 400 dermal exposures (most involving 40% HF) treated with immediate water irrigation, no patient developed deep tissue necrosis, and all recovered within days (4). Irrigation should be performed for a minimum of 20 minutes. If symptoms have not resolved, irrigation should be continued. Hexafluorine, a proprietary product that binds fluoride much more effectively than calcium, has been advocated, but it offers no clear advantage over irrigation with water.

Patients who have continued pain despite irrigation or who present several hours after the exposure should be treated in a stepwise fashion. Topical calcium is the standard first-line therapy. One effective way to deliver the calcium is to mix 10% calcium chloride with methylcellulose to form a gel with a final calcium concentration of 2.3% to 2.5%. If methylcellulose is not available, a water-based lubricant (e.g., KY jelly) may be used. The mixture is then applied topically to the affected area. Exposures involving the digits can be treated by having the patient wear a tight-fitting glove filled with the gel. The glove is worn for at least 30 minutes after the pain resolves. Fingernail removal is not advocated, and patients

with exposure that involves the nail beds are best treated with regional perfusion (see further). Patients who have pain relief may be discharged and apply the gel every 4 to 6 hours or sooner if needed, for the next 24 hours (5).

Patients who have continued pain despite topical calcium therapy should be treated with calcium injection or regional perfusion. Local subcutaneous injection of calcium gluconate is best suited for areas in which the tissue can expand to accommodate the fluid (e.g., trunk, scalp, proximal extremities, face). The dose is 0.5 cc of 10% calcium gluconate per cm^2 of involved skin. Calcium chloride should not be used, as it may cause tissue injury. The injection is performed with a small (27 g or smaller) needle. Successful treatment results in immediate improvement in symptoms (6). Use of a local anesthetic is not recommended as relief of pain is used to monitor of the effectiveness of therapy. Patients may be discharged with topical calcium gel therapy.

Often, the tissue on the hand, fingers, and foot cannot comfortably accommodate the volume of fluid during these injections. These areas are best treated by regional perfusion. This may be accomplished by either direct arterial injection or using intravenous injection with Bier technique. Arterial perfusion requires placing an arterial catheter. After confirming intra-arterial placement by either waveform or arteriography, 100 cc of a 2.5% calcium gluconate solution is infused over 60 minutes with a pump (7). An alternative to arterial infusion is regional venous calcium infusion using a Bier block. With this technique, an IV catheter is placed in the hand or foot, and the extremity is exsanguinated by elevation (with or without application of an elastic bandage). A pneumatic tourniquet is applied proximal to the IV site and the burn and inflated to 100 mm Hg above systolic blood pressure. Once the tourniquet is inflated, 10 cc of a 10% calcium gluconate diluted with 40 cc of saline is infused into the catheter in the affected extremity. After 15 to 25 minutes, the tourniquet is deflated slowly over 5 minutes (8). Most patients will require parenteral analgesia to tolerate the tourniquet.

Ocular exposures should be treated with immediate water irrigation. As with any caustic exposure to the eye, the ocular pH should be monitored. There is no evidence that irrigation with calcium or magnesium-containing solutions offers any advantage, and any delay that occurs while these solutions are obtained is likely to be detrimental. Although animal models suggest that severe injury is possible, reported cases have gone on to good recovery. One report suggested that calcium gluconate drops may be a useful adjunctive therapy after decontamination, but this is not routinely recommended.

Nebulized calcium gluconate (2.5%) has been used for inhalational exposures, but the evidence for this intervention is anecdotal and limited, so it cannot be considered standard.

Systemic fluoride poisoning may occur after exposure to many fluoride-containing products. The management of systemic fluoride poisoning does not vary depending on the type of fluoride or the route of exposure. Patients with ingestions of fluoride-containing products should rinse their mouth and drink 50 to 100 cc of water to dilute the caustic effects. Charcoal does not adsorb fluoride and should not be administered. Oral administration of calcium-containing solution is of unproven value. One animal model found a survival benefit but only when the ratio of calcium to fluoride exceeded a 1:1 equivalent ratio (9). This would translate to more than 3 g of calcium chloride for each gram of fluoride ingested. Accidental exposures to most nonprescription dental products that contain fluoride do not result in serious toxicity although patients may develop GI symptoms. Patients with small (suspect <30 cc ingested), accidental exposures to low-concentration HF products or dental sodium fluoride products almost always do well (3). Asymptomatic patients with small ingestions (e.g., a sip) should have venous access obtained and be placed on a cardiac monitor. Baseline calcium measurements should be obtained immediately. If the serum calcium is below the normal range, it is reasonable to administer 1 g of calcium gluconate over 30 minutes and then immediately repeat the calcium level. Persistent hypocalcemia suggests a significant exposure, and the patient should be treated as

if there were a deliberate exposure. Patients with deliberate ingestions or accidental ingestions suspected to involve more than 30 cc of low-concentration HF products or sodium fluoride may benefit from prophylactic treatment with intravenous calcium. Animal models suggest that such treatment improves survival. The author recommends that any patient who presents after deliberate ingestion of an HF product should be treated with prophylactic calcium gluconate (at a rate of 3 g/hr) after baseline serum calcium is measured. Calcium chloride may be used, but it must be given through a well-functioning line, as extravasation may cause extensive tissue injury. If the initial serum calcium is normal, the infusion may be stopped, but serum calcium levels should be measured every 30 minutes for at least 3 hours and, if calcium levels are decreasing, the infusion should be restarted.

Patients who develop hypocalcemia or any CV effects must be treated very aggressively. Survival after cardiac arrest from fluoride poisoning has always been associated with very aggressive calcium therapy. One patient suffered cardiac arrest and survived after the administration of more than 110 mEq of calcium chloride (approximately 9 g) during a resuscitation (10). Although only suggestive, this case suggests that early administration may prevent CV collapse. Patients who have or develop hypocalcemia, hyperkalemia, cardiac dysrhythmias, hypotension, coma, or seizures should have central venous access, and the calcium infusion should be changed from calcium gluconate to calcium chloride (which contains three times as much calcium per gram) and continued at the same rate using the central venous access. The serum calcium should be measured every 30 minutes and, if hypocalcemia persists, the calcium infusion rate should be doubled. Fluids should be administered for hypotension. Cardiac dysrhythmias and hyperkalemia may not respond to usual therapies. Magnesium and potassium levels should also be monitored, and magnesium should be administered to maintain a normal serum level. Sodium bicarbonate boluses and a sodium bicarbonate infusion have been used to alkalinize critically ill patients to a serum pH of 7.45 to

7.50, but although systemic alkalosis has improved survival in animal models, alkalinization is likely to worsen hypocalcemia.

DISPOSITION

Patients who present with dermal exposures that have no symptoms after irrigation may be discharged with instructions to return or begin topical calcium therapy if pain develops. Similarly, patients who present with pain and respond well to topical or intradermal therapy in the ED may be discharged with topical therapy every 4 to 6 hours and a 24-hour follow-up. If visible burns are noted, a burn or hand surgeon should be consulted. Patients who require regional infusions are likely to require repeat therapy and should be admitted for 24-hour observation. Intra-arterial administration is an indication for intensive care unit admission (primarily for monitoring of the arterial line).

Patients who have no symptoms and a normal examination after irrigation for ocular exposures may be discharged with next day follow-up. An ophthalmologist should be consulted for patients with persistent symptoms or an abnormal ocular examination emergently. Patients with ingestions of HF products who have no symptoms and normal serum calcium levels after 6 hours may be discharged or referred for psychiatric evaluation. Those who require intravenous calcium should be admitted to an intensive care unit for ongoing monitoring and treatment.

CRITICAL INTERVENTIONS

- Immediately irrigate dermal or ocular exposures with water or saline.
- Topical calcium chloride in a gel can relieve many patients.
- Administer s.c. calcium gluconate, followed by regional, intravenous, or intra-arterial calcium gluconate infusion, for patients who have skin findings or persistent pain after dermal exposure.
- Institute cardiac rhythm (and QT interval) monitoring and give prophylactic IV calcium gluconate to patients with intentional

ingestions or large dermal, inhalational, or oral exposure.
- Administer IV calcium chloride through a central line to patients with hypocalcemia or QT interval prolongation.

Common Pitfalls

- Failure to appreciate that patients with dermal HF injury may have pain without abnormal skin findings.
- Failure to appreciate that systemic fluoride poisoning after ingestion may occur in the absence of GI symptoms.
- Failure to appreciate that severe systemic fluoride poisoning may result from large dermal and inhalational exposures.
- Failure to appreciate that large doses of calcium and magnesium may be required in patients with systemic fluoride poisoning.

CHAPTER 331 Hydrocarbons

Kristine A. Nañagas and Laura M. Tormoehlen

Hydrocarbon is a term that covers a wide number of solvents and chemicals. Many are distilled petroleum products. Examples include: gasoline, mineral spirits, toluene, benzene, and xylene. They are commonly used as fuel, solvents, and carriers for other chemicals. Hydrocarbons are hydrophobic because of their high carbon and hydrogen content and tend to have an oily texture, but their more important properties include viscosity and volatility. More viscous substances are thicker; less viscous hydrocarbons are thinner and spread easily so that a small amount can cover a large surface, such as with furniture polish. Highly volatile chemicals become a gas easily and are prone to explosion (see Section IV), but also to inhalation, aspiration, and lung injury. Halogenated hydrocarbons contain fluorine, chlorine, bromine, or iodine, are typically excellent solvents (e.g. carbon tetrachloride or trichloroethylene found in dry cleaning fluids and refrigerants), but can cause liver disease with chronic exposure. As a solvent or carrier for other chemicals, metal-containing hydrocarbons such as leaded gasoline can cause additional toxicity.

Patients generally present in one of the four scenarios: (1) the toddler with a small accidental ingestion; (2) recreational inhalation for euphoria; (3) accidental ingestion of a small amount; or (4) intentional ingestion of a large amount by an adult. The degree of exposure and subsequent effects and symptoms vary depending on the volatility and viscosity, whether the exposure is inhaled, ingested, aspirated, or in contact with the skin, the presence of other additives, the degree of exposure, and the dose.

CLINICAL PRESENTATION

Neurologic: Hydrocarbons that are abused for euphoric effects via the respiratory route of exposure (e.g., toluene) are called inhalants. Organic solvents are readily accessible, as they are present in many household products. These products are frequently a mixture of solvents; however, toluene (in glue, lacquer, spray paint, etc.) is the substance that seems to have the highest abuse potential (1).

Misuse of volatile substances is popular among teenagers, owing to their wide availability and rapid effects. Of the 719,000 people (aged 12 or older) with first-time use of inhalants in 2011, about 67% were under 18 years of age (2). Of eighth graders surveyed in 2012, 11.8% had ever tried inhalants, 6.2% had used inhalants within the past year, and 2.7% had used within the past month (3). The abuse of inhalants may be predictive of future polysubstance abuse (1).

The chemical properties of the hydrocarbon determine its effect. Highly volatile compounds are more likely to be absorbed after inhalation. Those that are very lipophilic cross the blood–brain barrier more readily, and are more likely to result in central nervous system (CNS) effects. They also remain in the CNS longer, resulting in symptom duration that may persist after the exposure ends (1).

Acute hydrocarbon inhalation causes an initial euphoria that occurs within minutes of exposure. This can be followed by progressively worsening CNS depression, including: agitated delirium, hallucinations, ataxia, seizure, coma, and death. Associated signs can include nystagmus, hyporeflexia, tremor, and dysarthria. Some compounds are more likely than others to cause seizures, and camphor is particularly well known to cause rapidly occurring seizures. Overall, excitatory effects occur at lower doses, with sedating effects at higher doses. The exact mechanism of toxicity for each individual compound is not clear; however, toluene appears to cause both GABA-A stimulation and NMDA inhibition and may have effects at other receptors as well (1,4). Death by asphyxia can occur from airway occlusion by the plastic bags used in “bagging.” Impaired judgment from the acute intoxication can result in trauma or drowning, resulting in injury or death.

The long-term use of inhalants can result in progressive cognitive impairment. These symptoms, when associated with brain magnetic resonance imaging (MRI) changes, are termed leukoencephalopathy. Much of the literature on leukoencephalopathy in the setting of inhalant abuse is regarding toluene. Toluene abuse may also cause cerebellar and pyramidal tract dysfunction, and has been associated with cranial nerve deficits (including optic atrophy, tinnitus, and hearing loss) (5). Symptoms progress with continued use. Some authors have reported improvement after cessation of use, whereas others have observed persistent effects (6).

Toluene affects white matter to a greater degree than gray matter, which may be due to the high lipid content of the myelin that defines white matter. MRI changes with chronic toluene abuse include white matter lesions in 46%, ex-vacuo ventricular dilation in 27%, and hypointensity of the thalamus in 20%. The presence of white matter lesions and thalamic hypointensity were associated with greater than 4 years of abuse (7). Diffuse atrophy results in enlargement of the sulci and ventricles (see Fig. 331.1A,B) (6).

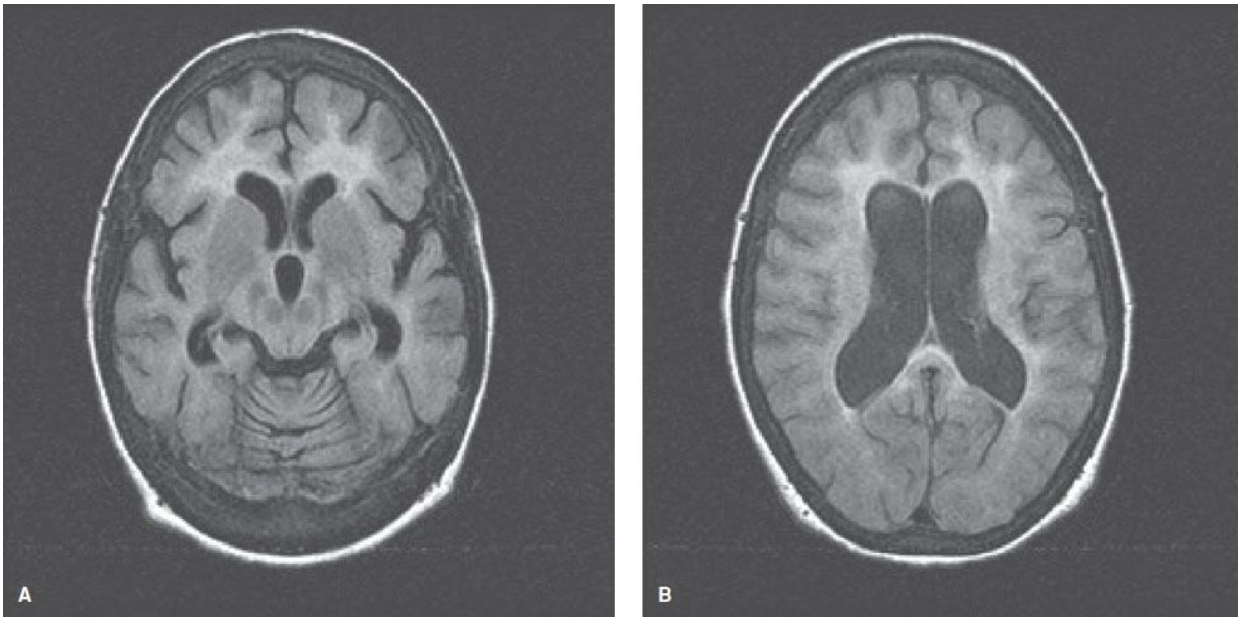

FIGURE 331.1 A, B: Toluene leukoencephalopathy. Axial FLAIR MRI of 27-year-old woman with history of chronic toluene abuse resulting in white matter changes and diffuse atrophy.

Neuropsychiatric testing of chronic toluene abusers reveals deficits in learning, memory, processing, attention, psychomotor tasks, and executive function. Compared to users of other drugs such as alcohol and cocaine, those who abused solvents had more impairment in both memory and executive function. These effects of chronic toluene use likely contribute to the higher risk of future polysubstance abuse, criminal behavior, and chronic psychiatric disease (6).

Ingestion of hydrocarbons rarely causes lethargy, seizures, coma, or other nervous system toxicity, but does present a risk of pneumonitis from aspiration.

Cardiac: Malignant arrhythmia (most commonly ventricular fibrillation) resulting in death is termed “Sudden sniffing death syndrome.” This scenario occurs in patients with a high concentration of hydrocarbon vapors, who are then suddenly excited or frightened. Dysrhythmias are more likely to occur with halogenated hydrocarbon (halocarbon) abuse. Experimental evidence shows that halocarbons induce arrhythmia by reducing gap junction conductance, hyperpolarizing cardiac cells (via blockade of potassium channels), inhibiting sodium channels, and altering calcium channel activity (8). These changes leave the heart vulnerable to catecholamine-induced after-depolarization and re-entrant arrhythmias (4).

Renal/Metabolic: Toluene intoxication causes renal tubular acidosis. Patients may present with generalized weakness, due to severe hypokalemia. There may also be muscle weakness and pain from rhabdomyolysis. Some patients report abdominal pain and vomiting.

Pulmonary: Aspiration pneumonitis is associated with high rates of morbidity and mortality. This occurs most often after an ingestion of a hydrocarbon by a toddler but also occurs after purposefully inhaling solvents, or trying to siphon gasoline. Hydrocarbons with high volatility and low viscosity pose the greatest risk for aspiration, as they can flow easily and penetrate deep into the distal airways. Examples of these substances are kerosene, mineral seal oil, lamp oil, gasoline, lighter fluid, and turpentine. Vomiting increases the risk of

development of pneumonitis, although aspiration can occur in the absence of vomiting. Symptoms of pneumonitis generally appear within 2 to 6 hours after aspiration, and include shortness of breath, fever, vomiting, and cough. More severe cases will present with grunting, wheezing, or cyanosis. Some patients will also have CNS symptoms secondary to hypoxia, independent of direct effects from the hydrocarbon (9).

Miscellaneous: Prolonged dermal contact with hydrocarbons can result in skin damage, ranging in severity from minor irritation to severe chemical burns. A rash surrounding the nose and mouth of chronic inhalant abusers is called “glue sniffer’s” or “huffer’s” rash and is secondary to a severe drying of the skin that may also allow secondary bacterial infection. Chronic dermal exposure to hydrocarbons, common at a worksite, may also result in a defatting injury. Patients who drink hydrocarbons may develop mucosal irritation, presenting as abdominal pain, nausea, and vomiting.

DIFFERENTIAL DIAGNOSIS

Intoxication from inhalant abuse can present similarly to the effects of GABA agonists (e.g., ethanol, benzodiazepines, GHB), anticholinergics, or opiates. The altered mentation is nonspecific and can be mistaken for trauma, meningoencephalitis, or systemic infection. Tachydysrhythmias and reentrant arrhythmias can occur with coronary artery disease, cardiomyopathy, electrolyte abnormalities, hypoxia, and numerous other drug and chemical exposures.

The differential of metabolic acidosis is broad, but includes methanol, ethylene glycol, salicylates, and iron poisoning. Hypokalemia can be from inadequate intake, excessive gastrointestinal loss, diuretic use, mineralocorticoid excess, or intracellular shift. Weakness from electrolyte disturbances can be mistaken for Guillain–Barré syndrome.

The respiratory symptoms of hydrocarbon aspiration can mimic reactive airway disease, pulmonary infection, or pulmonary embolism. Many other mucosal irritants produce the same

symptoms. Pulmonary infiltrates, fever, and leukocytosis secondary to aspiration of hydrocarbons may mimic an infectious process.

ED EVALUATION

After initial stabilization, a history should be obtained that includes the exact substances involved, route of exposure, and time course of ingestion. Hydrocarbon products which are ingested may contain additional toxins, such as heavy metals, pesticides, and camphor (see Chapters 318 and 326).

Symptomatic patients should be kept on a cardiac monitor. Soon after inhaled exposure, toluene is metabolized and hippuric acid forms to cause an increased anion gap acidosis. Patients can later have a normal anion gap metabolic acidosis, characterized by hyperchloremia, hypokalemia, and a high urine pH (10). Hypophosphatemia is frequently reported. Rhabdomyolysis may be present. Acute renal failure and hepatic impairment are rare complications. Patients with mild decreased level of consciousness will need observation, but patients with severe coma may need to be assessed for trauma and other causes of altered mental status.

When ingestion has occurred, the history should assess the risk of aspiration by noting manifestations such as cough, gagging, vomiting, or dyspnea. Continuous oxygen saturation monitoring should be considered to detect hypoxia. A chest x-ray should be taken for symptomatic patients, but since the findings on x-ray can be delayed, asymptomatic patients may be imaged after 6 hours to identify late infiltrates. The infiltrates seen with aspiration pneumonitis are usually interstitial and are generally bilateral (see Fig. 331.2). Hydrocarbon aspiration causes lung irritation and loss of surfactant, and can result in lipoid pneumonia (9). Leukocytosis is often present but is not necessarily indicative of an infectious process. A blood gas should be considered for those with respiratory distress.

FIGURE 331.2 Hydrocarbon-induced aspiration pneumonitis in a child.

KEY TESTING

- For inhalation, EKG and monitoring, BMP, urinalysis, calcium, magnesium, phosphorus
- For ingestion, CXR for possible aspiration; imaging if suspected head trauma
- For supportive care, CBC, BMP, LFT, CPK for suspected rhabdomyolysis

ED MANAGEMENT

For patients exposed to vapors, contaminated clothing should be removed and bagged, ideally before the patient enters the emergency department (ED). Affected skin should be cleaned gently with soap and water. Supportive care should be initiated, with special attention given to the neurologic, cardiac, and pulmonary organ systems. Patients may be at risk for dysrhythmia and sudden sniffing death.

For patients with altered mental status after inhalant abuse, most care is symptomatic and supportive. If seizure or agitation occurs, benzodiazepines should be used. Patients should be assessed for chemical dependency, and providers should recommend abstinence from further use.

After hydrocarbon ingestion, gastric decontamination is generally contraindicated, especially in cases where the hydrocarbon has a low viscosity and high volatility, as the risk of aspiration during decontamination is high. The presence of an endotracheal tube does not necessarily prevent aspiration. Emesis should also be avoided for the same reason. In rare cases, gastric decontamination may be considered, with either a nasogastric tube or activated charcoal. Not all hydrocarbons adsorb to activated charcoal but charcoal may be beneficial for a hydrocarbon solution containing dangerous additives, or for hydrocarbons with low risk of aspiration but high risk of systemic toxicity (e.g., carbon tetrachloride, methylene chloride, methylene bromide, trichloroethylene).

Airway stabilization should be the primary concern when managing a potential hydrocarbon aspiration. Supplemental oxygen may be required. For patients with inadequate oxygenation, severe respiratory distress, or alteration in consciousness, early intubation should be initiated. Positive end-expiratory pressure may be required to maintain oxygenation. For patients with wheezing or suspected bronchospasm, bronchodilators may be helpful. Steroids are not indicated. Antibiotics are not indicated as routine prophylaxis, and should not be used without clear and objective signs of infection, keeping in mind that infection is unlikely in the early stages of aspiration pneumonitis. No large-scale studies have been performed to show the most beneficial interventions for patients who have difficulty maintaining adequate oxygenation despite intubation. Case reports suggest use of surfactants, high-frequency jet ventilation, extracorporeal membrane oxygenation, or partial liquid ventilation.

Patients presenting with dysrhythmias should generally be treated with established cardiac guidelines. Catecholamines or sympathomimetics should be avoided so as to prevent ventricular fibrillation. Beta blockers are felt to be protective, and should be

considered in patients with dysrhythmias following acute hydrocarbon inhalant abuse.

Patients with renal tubular acidosis from toluene inhalation will need IV fluids and correction of electrolyte abnormalities and acid–base imbalance. They are likely to need potassium replacement. Those with rhabdomyolysis will need aggressive fluid support and alkalinization.

CRITICAL INTERVENTIONS

- Comprehensive laboratory workup for those with chronic inhalational exposure
- Cardiac monitoring and avoidance of catecholamines for those with inhalational exposure
- Assess those with intentional inhalation for chemical dependency
- Obtain chest x-ray in those with potential for hydrocarbon aspiration

DISPOSITION

Patients with sinus tachycardia after inhaling a hydrocarbon should be observed or admitted to a telemetry unit until the heart rate normalizes. Patients who have had a malignant arrhythmia should be admitted to an intensive care unit (ICU).

Patients with severe electrolyte abnormalities and anyone with weakness should be admitted to telemetry for electrolyte correction. Mild electrolyte changes generally resolve with cessation of abuse of toluene and some can be managed at home.

Patients who remain asymptomatic after aspiration and have a negative chest x-ray after 6 hours of observation may be released from the ED. Symptomatic patients who remain stable should be admitted to the hospital for observation. Indications for ICU admission include respiratory distress, altered mentation, or increasing oxygen requirement.

Common Pitfalls

- Failing to avoid catecholamine exposure in patients who have inhaled hydrocarbons.
- Failing to prevent emesis in those with hydrocarbon ingestion.
- Failing to recognize the potential severity of aspiration and the time lag of radiographic changes.

CHAPTER 332

Hydrogen Sulfide

Matthew D. Sztajnkrycer

Hydrogen sulfide (H_2S) is a colorless, highly lipophilic, irritant gas that is a potent inhibitor of the cytochrome oxidase system. Sources of naturally occurring H_2S include volcanoes, sulfur springs, mines ("stink damp"), and natural gas deposits ("sour gas") (1). More than 70 occupations have been identified with potential for H_2S exposure (1,2). The term *sewer gas* refers to the production of H_2S through anaerobic decomposition of sulfur-containing proteins, found in sewage and manure. After carbon monoxide poisoning, H_2S is the second leading cause of occupational toxin-related deaths. The predominant source of occupational exposure is oil and gas exploration (3). More recently, H_2S has been utilized as a means of chemical suicide, placing first responders at risk (4).

The odor threshold for H_2S ranges between 0.02 and 0.13 ppm (5). By 20 to 30 ppm, H_2S demonstrates a characteristic odor of rotten eggs. Olfactory fatigue, the point when the nose acclimatizes to the odor, occurs at levels of 100 to 150 ppm, although olfactory paralysis occurs rapidly at higher levels. Loss of ability to perceive the noxious odor may be incorrectly interpreted as dissipation of the gas, resulting in prolonged exposure to elevated levels. Levels greater than 300 ppm are considered immediately dangerous to life and health. Levels as high as 1,000 ppm occur in manure slurry tanks, resulting in the immediate deaths of farm workers and rescuers (5,6).

After absorption, H_2S is widely distributed throughout the body. Similar to cyanide, H_2S forms complexes with ferric ion–containing metalloenzymes, including cytochrome-aa_3, thereby inhibiting oxidative phosphorylation and causing cellular asphyxia. Although H_2S is a more potent inhibitor of cytochrome-aa_3 than cyanide, cyanide has a 200-fold greater binding affinity. As a result, cytochrome-aa_3 inhibition by H_2S is more readily reversible than cyanide (1).

CLINICAL PRESENTATION

Exposure to H_2S can cause both local irritant or systemic effects. Keratoconjunctivitis was first described in petroleum industry workers, at levels of 50 to 100 ppm. Symptoms include eye pain, burning, lacrimation, and mucopurulent drainage (5). Blurred vision and colored halos around lights ("gas eyes") have been attributed to corneal edema and inflammation. Corneal ulceration occurs with severe exposure (5).

Prolonged exposure to H_2S at concentrations as low as 50 ppm causes respiratory mucosal irritation and inflammation. The upper and lower respiratory tracts are equally affected resulting in pharyngitis, rhinitis, bronchitis, and pneumonitis. Symptoms include sore throat, nasal congestion and drainage, hoarseness, cough with occasional bloody sputum, and shortness of breath. Symptoms are more severe with longer duration of exposure. Pulmonary edema occurs after prolonged exposure to concentrations >250 ppm and occurs more rapidly at levels of 300 to 500 ppm (7). Autopsy findings have noted hemorrhagic pulmonary edema and scattered pleural petechial hemorrhages. In contrast to cyanide and carbon monoxide poisoning, cyanosis is frequently described in H_2S intoxication (8). The exact etiology remains unclear.

Systemic effects of H_2S exposure are predominantly from central nervous system (CNS) dysfunction. At lower concentrations, CNS effects of H_2S intoxication are nonspecific and reflect progressive cellular hypoxia. Signs and symptoms include headache, anxiety,

dizziness, ataxia, confusion, vertigo, seizures, lethargy, and coma. With acute, high-level exposure, CNS effects predominate over the delayed local irritant and inflammatory effects. Levels >200 ppm are associated with CNS depression, and levels between 700 and 900 ppm are associated with rapid loss of consciousness ("knock-down") and respiratory paralysis. Seventy-five percent of occupational exposures have loss of consciousness at the site of exposure (7).

DIFFERENTIAL DIAGNOSIS

H_2S exposure is suspected from the rapid loss of consciousness (knock-down), and the odor of rotten eggs, which can off-gas from clothing, blood, exhaled air, and gastric secretions (9). Blackened copper and silver coins or jewelry after exposure to H_2S is another clue. The differential diagnosis includes other cellular asphyxiants (e.g., cyanide, carbon monoxide, sodium azide), simple asphyxiants (e.g., methane, carbon dioxide, helium, nitrogen), pulmonary irritants (e.g., ammonia, nitrogen dioxide), and acquired dyshemoglobinemias (e.g., methemoglobinemia). Other causes of a rotten egg odor include mercaptans, disulfiram, and sulfur dioxide. Other knock-down agents include carbon disulfide, organophosphates, acetylene, and carbonyl sulfide (2).

Other etiologies of syncope and collapse must be considered, including cardiovascular, neurologic, thromboembolic, and hypoglycemic causes. Concomitant occult traumatic injury must always be considered (7,9). In one review, 27% of H_2S intoxicated patients had associated trauma. The differential diagnosis of dermal irritation includes contact dermatitis, photosensitivity reactions, trauma, infection, and vasculitis.

ED EVALUATION

Despite loss of consciousness at the scene, patients may be asymptomatic or minimally symptomatic on arrival at the emergency department (ED) (1,7,9). Initial history is directed toward confirming H_2S exposure and the severity of symptoms prior

to arrival. Important historical information includes location and actions preceding symptom onset, duration of exposure, time course of any alterations in level of consciousness, and any unusual odors noted. The possibility of coexistent trauma should also be addressed.

After evaluation of vital signs, the physical examination should focus on assessment for irritant (ocular, dermal, mucous membrane, pulmonary) and systemic (cardiovascular and neurologic) effects. A thorough neurologic examination, including mental status testing and neuropsychiatric screening batteries, if available, should evaluate for subtle neurologic dysfunction.

No tests are available to confirm the diagnosis of H_2S poisoning (2). Patients with limited irritant symptoms, normal vital signs, and normal physical examinations require no laboratory assessment. Patients with systemic toxicity should have a chest radiograph, electrocardiogram, and arterial blood gas analysis for evaluation of oxygenation and acid–base status. Anion gap metabolic acidosis and elevated serum lactate levels reflect the underlying cellular asphyxia. Occasionally, oxygen saturation gaps attributed to sulfhemoglobin may occur. Routine hematology and chemistry profiles may assess the general condition. Patients with prolonged loss of consciousness, persistent alteration in level of consciousness, or focal neurologic deficits may require radiologic imaging to evaluate for cerebral ischemic insult and trauma.

KEY TESTING

- Most patients do not need any testing.
- Evaluation of systemic symptoms includes CXR, ECG, ABG.

ED MANAGEMENT

Initial management involves removing the patient from the source of exposure. Survivors frequently improve simply with this intervention (3,7). Rescuers should not attempt to enter the environment of exposure without wearing self-contained breathing apparatus. Nearly one-fourth of occupational deaths are the result of rescue attempts (1,2,7,8). ED decontamination should include

removal of grossly contaminated clothing and cleansing with soap and water to limit local irritant effects. Ocular irrigation and the removal of contact lenses may be needed to decontaminate eye exposure.

Supportive care is the mainstay of treatment for systemic toxicity, with specific attention to advanced life-support, and management of altered mental status, pulmonary edema, hypotension, acidosis, and concomitant trauma. Supplemental oxygen (100%) enhances oxygen delivery and increase endogenous sulfide metabolism (10).

Specific data regarding antidotal therapy remain sparse and controversial. Similarities with cyanide intoxication led to the use of sodium nitrite in severe H_2S intoxication. Anecdotal reports and pretreatment animal models have demonstrated improvement with nitrite therapy (2); however, no convincing evidence exists that nitrite actually improves patient outcome or changes clinical course. In vitro time-course studies indicate that nitrite must be administered within minutes of exposure to be effective (3). In addition, the induction of methemoglobinemia by nitrites may further impair oxygen transport and worsen the clinical situation. Nitrite therapy remains recommended for patients with severe H_2S intoxication who do not rapidly improve on removal from the source, and the nitrite should be administered within 1 hour of exposure. The dose of sodium nitrite is identical to that used for cyanide (see Chapter 329). Sodium thiosulfate is not recommended. Improvement with hyperbaric oxygen (HBO) therapy has been reported, even in nitrite-refractory H_2S poisoning (2,10). HBO should be considered for severely intoxicated patients with persistent neurologic abnormalities, especially those patients unresponsive to supportive care or nitrite therapy.

CRITICAL INTERVENTIONS

- Rapid extrication of the victim from the source.
- Aggressive supportive care is the mainstay of therapy.
- Search for concomitant trauma.
- Consider sodium nitrite or HBO in severely intoxicated patients.

DISPOSITION

Patients presenting after a minor H_2S exposure may be discharged after a 4- to 6-hour observation period. Patients with toxicity limited to dermal or ocular irritation may be managed as outpatients. Patients with significant exposure (including loss of consciousness) or local airway irritation should be monitored for at least 24 hours. Patients with abnormal vital signs and cardiopulmonary and neurologic examinations should be admitted to an intensive care unit. Patients with initial loss of consciousness should be followed up within 1 week for examination for delayed neuropsychiatric sequelae. Transfer of severely intoxicated patients should be considered if intensive care or nitrite therapy is indicated but unavailable.

Common Pitfalls

- Failure of the prehospital rescuer to wear self-contained breathing apparatus and becoming an additional victim.
- Failure to consider H_2S poisoning in healthy patients who suddenly collapse at work.
- Failure to appreciate that lack of an odor does not imply safety.
- Failure to perform a scene search for other victims when an index case is found.
- Failure to anticipate delayed pulmonary injury in the minimally symptomatic patient.

CHAPTER 333

Iron

Michael R. Christian and D. Adam Algren

Although iron poisoning occurs in all age groups, it has been a leading cause of accidental poisoning death from pharmaceutical agents among young children. Household sources of iron are common and readily available for impulsive ingestions. Parents' iron supplements are often found in homes with toddlers; many of these preparations resemble candy, and some are even candy-coated. Chewable multivitamins with iron are specifically designed to appeal to young children. A dramatic decline in pediatric iron overdose deaths followed the 1997 Food and Drug administration (FDA) mandate that iron supplements be packaged in blister packs. This was combined with warning labels and public educational campaigns. After a long legal battle with pharmaceutical companies, the FDA rescinded this requirement in 2003. Fortunately, there has not been a significant rebound in the number of pediatric iron overdose deaths since 2003.

The amount of iron in each preparation varies, and toxicity after acute ingestion depends on the amount of elemental iron ingested (Table 333.1). In general, the ingestion of more than 20 mg of elemental iron per kilogram of body weight produces significant gastroenteritis; doses above the 40- to 60-mg/kg range are potentially fatal. Although confirmatory studies are lacking, children's chewable multiple vitamins with iron rarely cause severe iron poisoning and are less toxic than expected on the basis of elemental iron ingested per body weight (1). Some poison centers observe asymptomatic or only mildly symptomatic children at home after ingesting such preparations, even when the estimated ingestion

exceeds 20 mg/kg of elemental iron. In addition, newer nonionic iron formulations like carbonyl iron and iron polysaccharide have not been observed to cause significant toxicity in children.

TABLE 333.1
Common Iron Compounds and their Percent Elemental Iron Content

Common Iron Compounds and their Percent Elemental Iron Content	
Compound	**Percent Elemental Iron by Weight**
Ferrous sulfate	20
Ferrous fumarate	33
Ferrous gluconate	12

The human body cannot excrete iron so homeostasis relies on gastrointestinal (GI) absorption of iron, which is increased or decreased depending to the body's needs. Normally, about 10% of ingested iron, mainly in the ferrous (Fe^{2+}) state, is absorbed each day from the small intestine. Because free, unbound iron is toxic to tissue, the body has several mechanisms to keep iron bound to proteins or other macromolecules. After absorption, iron changes to the ferric (Fe^{3+}) state and is stored in the intestinal mucosa complexed to ferritin. Transport to other tissues occurs with iron bound to transferrin. The total amount of iron that transferrin can bind is termed the total iron-binding capacity (TIBC). Normal serum iron concentrations vary from 50 to 150 μg/dL, although normal TIBCs can range from 300 to 450 μg/dL. Because the TIBC is far in excess of the iron concentration, there is no circulating unbound iron under normal circumstances.

Excessive iron is corrosive to the GI tract, resulting in gastroenteritis, with the potential for hemorrhage, hypovolemia, and perforation. If enough iron is absorbed, systemic and metabolic consequences of iron poisoning develop. Iron accumulates mainly in the liver after overdose but can have toxic effects in almost any organ. Iron is concentrated in mitochondria, wherein it disrupts

oxidative phosphorylation and catalyzes the formation of oxygen-free radicals, leading to lipid peroxidation and cell death. Toxic amounts of iron also produce venodilation and increase capillary permeability. The metabolic acidosis seen in iron poisoning is from hypovolemia, tissue hypoperfusion, a shift to anaerobic metabolism as mitochondrial function is impaired, and the hydration of the ferric ion with generation of hydrogen ions:

$$[Fe^{3+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+]$$

Even before the onset of hepatic dysfunction, coagulopathy may occur from iron's inhibition of serine proteases, such as thrombin, and other coagulation factors. Isolated liver damage may occur, but multiple organ system failure is typical in severe iron poisonings (2).

CLINICAL PRESENTATION

Clinical effects of iron poisoning are usually considered in stages (2). However, patients present at different times after ingestion, the time frame for staging is imprecise, and it can be difficult to distinguish between stages because of rapid progression and overlapping signs, symptoms, and laboratory manifestations. Patients can die in any stage of iron poisoning but for different reasons.

The first stage develops within the first few hours after ingestion, as a result of the direct corrosive effects of iron on the GI tract, and is characterized by abdominal pain, vomiting, and diarrhea. Diarrhea may be the only manifestation in patients who ingest multiple vitamins with iron, particularly preparations intended for children. Hematemesis or melena may occur if there is significant GI bleeding. Patients with serious toxicity develop lethargy, shock, and metabolic acidosis as a result of hypovolemia, anemia, and tissue hypoperfusion. Serum iron concentrations may be normal or elevated.

With the second stage, GI symptoms resolve despite continued absorption of iron and increasing tissue iron burden. This stage may last until about 24 hours after ingestion. Patients may appear

clinically improved, but this can be falsely reassuring. Laboratory studies are likely to show elevated serum iron levels and a progressive metabolic acidosis.

In the third stage, systemic iron poisoning becomes clinically evident. This may occur early in patients with severe poisoning (bypassing stage 2). Toxic amounts of iron have now moved from blood into tissues, disrupting cellular metabolism, causing third-spacing of fluids and producing venous pooling of blood. Shock and metabolic acidosis in this stage can result from hypovolemia, anemia, hepatic dysfunction, impaired oxidative phosphorylation, heart failure, and renal failure. Fulminant hepatic failure with hypoglycemia, hyperammonemia, and coagulopathy may occur, although significant hepatic injury is unusual if peak serum iron levels remain below 500 μg/dL.

The fourth stage is an unusual occurrence several weeks after the acute toxicity has resolved, characterized by gastric outlet obstruction or small-bowel obstruction, which can develop as a result of scarring produced by iron's corrosive effects.

Elevated serum iron levels obtained near their peak, at 4 to 6 hours after ingestion, confirm the diagnosis of iron poisoning and may predict severity. A serum iron level drawn early after ingestion may be misleadingly low if absorption is still occurring. A normal serum iron level may occur in seriously ill patients many hours after ingestion after the iron has been distributed from the serum to the tissues, where it produces systemic toxicity. Therefore, a normal serum iron concentration obtained too early or too late after ingestion does not exclude iron poisoning.

Although sometimes elevated, the white blood cell count ($>$15 k/mm^3) and serum glucose concentrations ($>$150 mg/dL) are not of sufficient sensitivity to assess the severity of acute iron poisoning (3). The "deferoxamine challenge" test, in which the presence of vin rosé–colored urine after giving a dose of deferoxamine was considered an indication for chelation therapy, is no longer recommended because it is unreliable (4). An abdominal radiograph may demonstrate radiopaque tablets in the GI tract, a finding often present in patients who develop serious poisoning. However, a

normal radiograph does not exclude a significant ingestion. Even when iron tablets are noted initially, they are usually no longer visible at 24 hours.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of patients presenting with GI symptoms includes infectious gastroenteritis, medical and surgical intra-abdominal conditions, or sepsis that may cause vomiting, diarrhea, acidosis, and shock. Acute iron poisoning is not typically accompanied by fever unless a complication such as aspiration or bowel infarction develops. Iron poisoning can mimic intussusception with an ill-appearing toddler with occult fecal blood. Other toxicologic etiologies with a similar presentation include poisoning by acetaminophen, salicylate, hepatotoxic mushrooms, arsenic, caffeine and theophylline, caustics, copper salts, and mercurial salts.

ED EVALUATION

The history should include the time and the nature, severity, time of onset, and progression of symptoms. The physician should specifically ask about abdominal pain, vomiting, and diarrhea and the presence of blood. The amount of elemental iron ingested, in milligrams per kilogram, should be calculated from the amount of ingestion, and the identity of the iron preparation (see Table 333.1). The physical examination should focus on vital signs, overall appearance, and the abdomen.

Patients who have had only one or two episodes of vomiting or diarrhea and are subsequently asymptomatic should have a complete blood count (CBC) and measurement of serum electrolytes, glucose, blood urea nitrogen, creatinine, iron levels, and an abdominal radiograph. Those with abdominal pain or persistent GI symptoms, evidence of hypovolemia, or lethargy should also have liver function studies, serum lactate, prothrombin time, partial thromboplastin time, and blood gas analysis. Because measure of the TIBC is inaccurate in the setting of iron overload it is not helpful in the evaluation of iron toxicity (5).

KEY TESTING

- Obtain a CBC, serum electrolytes, glucose, blood urea nitrogen, creatinine, a serum iron concentration, and abdominal radiograph in patients who ingest >20 mg/kg of elemental iron OR are symptomatic.
- Consider serial iron concentrations in patients with significant symptoms until iron levels peak.
- Obtain liver function studies, serum lactate, prothrombin time, partial thromboplastin time, and blood gas analysis in patients with significant GI symptoms, hypotension, or lethargy.

ED MANAGEMENT

Activated charcoal does not effectively bind iron. Gastric lavage has not been shown to be of clinical benefit, possibly because most iron tablets are too large to evacuate. Simulated overdose studies suggest that oral magnesium oxide (milk of magnesia, 60 mL/g of elemental iron ingested) (6) or a slurry of charcoal mixed with deferoxamine (7) can reduce iron absorption, but the utility of such treatments in actual overdose patients is unknown.

Patients who remain completely asymptomatic (including absence of lethargy) for 6 hours after ingestion and have a normal physical examination do not require treatment.

Those who ingested >20 mg/kg of elemental iron but are seen within 6 hours might benefit from whole-bowel irrigation. Radiography demonstrating numerous tablets suggests that serum iron concentrations will rise and whole-bowel irrigation with a polyethylene glycol-electrolyte solution has been used with good results, although controlled studies are lacking (8). The empiric adult dose starts at 2 L/hr and pediatric dosing at 20 mL/kg/hr and adjust as tolerated until clear rectal effluents.

If the serum iron concentration in an asymptomatic patient is <350 μg/dL and a repeat serum iron level shows no rise in the iron level, the patient can be safely discharged. Patients who have had only one or two episodes of emesis or diarrheal stool but who have remained asymptomatic for several hours and have a normal

physical examination, abdominal films, and laboratory evaluation do not require further treatment.

Patients with more than two episodes of emesis or diarrhea or evidence of hypovolemia or exhibit lethargy require treatment with fluids and chelation therapy with deferoxamine mesylate. Typically, chelation is also recommended in patients with a serum iron concentration greater than 500 μg/dL at 4 to 6 hours postingestion. In patients with significant symptoms, treatment should not be delayed to wait for results of a serum iron determination, because the therapy is indicated regardless of the serum iron concentration. Iron ingestion can raise the serum iron level above the normal range, and an elevated iron level alone does not constitute an indication for deferoxamine or admission in the absence of clinical signs of toxicity.

With rare exceptions, all symptomatic patients are hypovolemic. IV fluid challenges of 20 mL/kg of normal saline or lactated Ringer's are given to restore fluid volume and ensure a normal urine output. Patients commonly require maintenance infusions at twice normal rates to keep up with GI losses and third-spacing.

Deferoxamine mesylate can remove iron from tissues and nontransferrin-bound iron from plasma. Deferoxamine binds to iron to form ferrioxamine, which is excreted in the urine over days to weeks. Ferrioxamine occasionally imparts a vin rosé color to the urine, but this color change is inconsistent and should not be used to determine the need for additional treatment (2,4). Deferoxamine mesylate can be mixed in any crystalloid and should be continuously infused intravenously at 15 mg/kg/hr. Higher infusion rates can be tried in severe cases but are sometimes associated with hypotension (presumably from histamine release); this is rare with infusion rates below 45 mg/kg/hr, and resolves with slowing the infusion. Intramuscular deferoxamine is not recommended.

Many statements in the manufacturer's package insert for deferoxamine do not reflect currently accepted treatment practices. Deferoxamine is not contraindicated for the treatment of acute iron poisoning in pregnancy. Animal data and human experience strongly suggest that neither toxic amounts of maternally ingested

iron nor deferoxamine or ferrioxamine cross into the fetal circulation (9). Fetal death results from maternal demise, and a pregnant woman should be treated in the same way as any other patient. At 15 mg/kg/hr, many patients receive well in excess of 6 g deferoxamine mesylate each day, which is safe for the short-term treatment of iron poisoning.

Deferoxamine causes serum iron concentrations to be falsely low (10), which should not be a cause for stopping chelation therapy. Intravenous deferoxamine should be continued until clinical toxicity has resolved, serum iron levels are normal or low, and vin rosé–colored urine (if ever present) disappears (2). Most patients require 12 to 24 hours of deferoxamine infusion, but occasional patients with very large overdoses require more prolonged therapy. Use of hemodialysis in addition to a deferoxamine infusion after massive overdose has been reported but experience is limited. The use of prochlorperazine (Compazine) and deferoxamine together has produced coma in humans and this drug combination should be avoided.

CRITICAL INTERVENTIONS

- Administer intravenous normal saline and deferoxamine to patients with significant GI symptoms, hypotension, lethargy, and/or a 4- to 6-hour postingestion serum iron level greater than 500 μg/dL.
- Consider whole-bowel irrigation when radiopaque tablets are seen on radiographs.

DISPOSITION

Patients who remain completely asymptomatic or those with a normal physical examination, normal abdominal radiograph, and laboratory evaluation and only one or two episodes of emesis or diarrhea and then remain asymptomatic 6 hours after ingestion can be discharged.

Patients with mild symptoms should have repeat laboratory studies demonstrating no rise in the serum iron level and no

evidence of metabolic acidosis before being cleared for discharge. Symptomatic patients should be admitted. The level of monitoring and treatment required usually necessitates admission to an intensive care unit. If serum iron levels or deferoxamine chelation therapy is not available, the patients should be transferred to a facility in which such services are available.

Common Pitfalls

- Failing to administer adequate amounts of IV fluids.
- Waiting for the serum iron level before administering deferoxamine to a symptomatic patient.
- Using the TIBC for evaluation and treatment decisions.
- Sending patients home during the second stage of poisoning because they appear clinically improved.
- Assuming that a normal iron level, serum glucose, white blood cell count, deferoxamine challenge, and abdominal x-ray exclude significant iron poisoning.
- Giving prochlorperazine (Compazine) and deferoxamine together.
- Failing to appreciate that deferoxamine may falsely lower serum iron concentration.

CHAPTER 334

Lead

Steven M. Marcus

While public health efforts have successfully decreased the incidence of significantly elevated blood lead levels it is important to be aware of the possibility of exposure and to rule it out when symptoms and signs either suggest it or are so confusing that a definitive diagnosis cannot be made (3). Populations that might be considered at greatest risk are those occupationally exposed to sources of lead and the immigrant population that may have been exposed before immigrating or may have brought their source of lead with them in the process (5). The other population of importance is those individuals with retained metallic foreign bodies, such as veterans who may carry significant caches of lead bullets and other fragments in their muscle masses.

CLINICAL PRESENTATION

Patients with lead poisoning may present with nonspecific symptoms as headache, fatigue, malaise, abdominal pain, constipation, and vomiting. The abdominal pain is usually colicky and not responsive to standard analgesics. There may be complaints of peripheral paresthesias or hypoesthesias and occasional frank neurologic symptoms (e.g., wrist or ankle drop). The classic wrist drop more common in the dominant arm was seen in painters. Muscle weakness may also be noted. Depression and other affective disorders as well as erectile dysfunction have been reported in lead-poisoned adults (4). Hyperactivity, delayed development, or loss of

recently acquired skills may be seen in children with coma and seizures in severe cases.

Physical examination is generally unrevealing, although the blood pressure may be elevated. Occasionally, in adults with poor dental care, there may be a lead line, a dark bluish black discoloration of the gingiva at the dental border. This finding is rarely present in children or in adults with good dental hygiene. If increased intracranial pressure accompanies lead encephalopathy, examination of the optic fundi may show papilledema. Cardiac dysrhythmias such as premature ventricular contractions are reported.

An abdominal radiograph may detect radiopaque foreign bodies in patients with pica or accidental lead ingestion. In developing children, long-bone radiographs may show an increased density of metaphyseal growth plates as a result of disordered calcium deposition resulting in “lead lines.” This finding may persist into later childhood or adolescence but is rarely present in adults.

The laboratory usually reveals a hypochromic microcytic anemia. Lead may produce a nonautoimmune hemolytic anemia with increased red cell fragility and an elevated reticulocyte count. Basophilic stippling and eosinophilia are less often noted. Proteinuria, glycosuria, a Fanconi syndrome (with aminoaciduria and renal tubular acidosis), and increased blood urea nitrogen and creatinine levels may be seen in patients with lead nephropathy. Because lead reduces the excretion of uric acid, adults with lead toxicity are at risk to develop gout.

Although generally not available on an emergency basis, the definitive diagnosis of lead poisoning depends on the measurement of whole-blood lead which often also guides treatment. Lead levels as low as 5 μg/dL have been reported to produce biochemical abnormalities and, in children, may be associated with decreased intelligence and neurobehavioral problems (1,2). Lead levels above 10 μg/dL in children and above 40 μg/dL in adults are currently considered to be evidence of increased lead absorption serious enough to warrant intervention.

DIFFERENTIAL DIAGNOSIS

Lead poisoning can be called the great imposter, as the symptoms and signs are often obscure and resemble a host of medical and psychiatric illnesses and patients with risk factors for lead exposure should be evaluated. Lead poisoning shares symptoms with other heavy metal poisonings. The peripheral neuropathy from lead, more often seen in adults than children, tends to be more motor than sensory. Unlike arsenic, the peripheral neuropathy from lead is associated with decreased sensitivity; with arsenic, there are painful paresthesias. The "hallmark" of thallium poisoning is burning paresthesias and hair loss. Both lead and mercury poisoning are characterized by personality changes. Mercury intoxication is characterized by "erythrism" and rapid changes in affect, with outbursts of anger alternating with happiness. Lead poisoning is more often accompanied by depressive disorders.

ED EVALUATION

Patients who present to the emergency department (ED) with multisystem complaints, particularly chronic abdominal symptoms that have not responded to standard conservative therapy, should be suspected of having lead poisoning. The patient's occupation, hobbies, use of herbal or other folk remedies, or living conditions may suggest exposure to lead. Subtle changes in bowel habits, behavior, mood, and cognitive function and headaches, weakness, and paresthesias are nonspecific but provide supporting clues.

In addition to vital signs and a general physical examination, a detailed neurologic examination should be performed, including assessment for papilledema and gingival pigmentation. If recent lead ingestion is suspected, an abdominal radiograph showing a radiopaque object in the intestinal lumen may be helpful. In children, long-bone radiographs (knee and wrist) may reveal thickening of the growth plate from growth arrest and suggest chronic lead exposure. The laboratory evaluation should include a complete blood count, whole-blood lead, and free erythrocyte protoporphyrin (FEP) levels, serum blood urea nitrogen and

creatinine levels, and a urinalysis. Care must be taken to use lead-free collection techniques when measuring lead levels.

Unless a patient is symptomatic with a high suspicion of lead poisoning, blood lead levels should be confirmed before initiating treatment. Conversely, a patient presenting with symptoms and signs consistent with lead poisoning and a history suggestive of lead exposure should begin therapy immediately, to avoid any delay which may have serious effects on survival.

In some cases, a patient is referred to the ED with a known exposure or a known elevated blood level of lead. These patients need a baseline assessment and a decision whether chelation is necessary. When children are brought to the ED because parents are concerned about a possible exposure to lead contaminated toys, a blood level can be obtained and referral made for further management. If an acute ingestion is suspected, a plain film can be obtained to identify the need for whole-bowel irrigation.

KEY TESTING

- Blood lead level: use lead-free blood collection tubes
- Complete blood count
- If evidence of anemia workup to include, reticulocyte count, bilirubin direct and total, serum haptoglobin ferritin
- Basic metabolic profile with electrolytes, renal and hepatic functions, uric acid, and serum osmolarity

ED MANAGEMENT

It is increasingly unlikely to see a child, or adult, with acute, symptomatic lead poisoning. More likely, the physician is confronted with a child and his/her parent bearing a note stating the child's blood lead level. Since the primary treatment of lead poisoning is separation from the source of lead, unless the source is obvious, the most likely action will be to facilitate the individual's admission and environmental intervention.

Critical cases of acute poisoning with cerebral edema should be treated by hyperventilation, elevation of the head, and restriction of

fluids. Seizures should be controlled with pharmacologic agents such as benzodiazepines and barbiturates. In patients with acute encephalopathy (with or without coma or seizures), chelation therapy should be initiated before obtaining confirmatory laboratory data, because the long-term outcome is related to the length of time the vital organs are exposed to elevated lead levels. Although there is little science to prove efficacy or any alteration in outcome, whole-bowel irrigation may be considered if there is radiopaque material in the intestine, but decontamination should not delay parenteral chelation therapy in a symptomatic patient. Because there is controversy that oral chelation may increase absorption of lead, it should not be done in asymptomatic patients if there is lead within the proximal intestinal lumen (lead in the sigmoid colon or rectum is considered unabsorbable and not a risk).

Although there are no randomized clinical trials reporting the use of chelation, the standard of care since the late 1960s, is to treat all children with elevated lead levels that might cause neurologic damage. That range has varied over time depending on prevailing data. Currently, the FDA licensed indication for oral chelation therapy with succimer is for children with lead levels >45 μg/dL. Although not FDA licensed specifically, chelation is often recommended for adults with blood lead levels >80 μg/dL, and for patients with lower levels who have evidence of lead-associated symptoms or signs.

Dimercaprol (British Anti-Lewisite [BAL]) crosses the blood–brain barrier and forms a tight bond with lead; in patients with lead encephalopathy, it is the initial therapy of choice. An oil-based solution of dimercaprol is given intramuscularly in a usual dose of 3 to 5 mg/kg every 4 to 6 hours. BAL is suspended in peanut oil, so for patients with a history of peanut allergy, a test dose of BAL is **not** recommended since anaphylaxis could occur even with a test dose. Alternative treatment would then be recommended. Dimercaprol is painful when injected, and foul-smelling. Sterile abscesses may occur at the site of dimercaprol injection, and febrile responses are common. Many patients complain of lightheadedness and a terrible taste in their mouth.

Calcium disodium ethylenediaminetetraacetic acid ($CaNa_2EDTA$, also known as calcium disodium versenate) is water-soluble and can be given IM or IV. The lead-EDTA bond is very strong and stable at a physiologic pH. However, in acid urine, the bond is less stable, and there is the potential for release of free lead into the renal tubule and subsequent renal tubular damage. The main side effects of EDTA are phlebitis (with concentrations >0.5 mg/mL) and potential renal toxicity. IV administration is preferred because IM injections are extremely irritating and produce elevations of creatine phosphokinase. If the intramuscular route is used, pain is decreased with procaine or lidocaine, usually added to produce a 0.5% concentration of the local anesthetic.

$CaNa_2EDTA$ dose of 50 mg/kg/d may be given as a continuous IV drip. At a concentration of 0.5 mg/mL, a large amount of fluid must be infused. However, if the patient can tolerate the fluid load, the incidence of side effects, particularly renal dysfunction, may be decreased. IM $CaNa_2EDTA$ is given in divided doses every 4 to 24 hours. Because the use of $CaNa_2EDTA$ alone may liberate bone lead and transiently raise brain lead levels and increase symptoms, it is advisable to start with an initial dose of dimercaprol in symptomatic patients and those with high blood lead levels (>55 μg/dL in children and 100 μg/dL in adults).

Oral chelation with dimercaptosuccinic acid or succimer (Chemet) may be indicated for children with lead levels above 45 μg/dL and is as effective in clearing lead as the combination of dimercaprol and EDTA. The side-effect spectrum is minimal, with a small incidence of skin rash, transaminase elevations, and GI discomfort. Although not officially licensed for adults, it has been used because of its effectiveness, combined with its low order of toxicity. The published dosage in children is safe in adults—10 mg/kg/dose every 8 hours for 5 days, followed by 10 mg/kg/dose every 12 hours for an additional 14 days. Patients should be monitored for toxicity with weekly blood counts, chemistry profiles, and urinalysis. The presence of ketones in the urine may be used as a measure of compliance, because it is a very common accompaniment of

successful treatment. A mild rash or mild transaminitis is usually not a reason to abandon therapy but requires more frequent observation. It is important to ensure that no further exposure to lead occur while on oral chelation. There is no data demonstrating any long-term improvement in children treated with succimer, and a controlled, randomized clinical trial study funded by the National Institute for Environmental Health Sciences treating children with blood lead levels between 25 and 45 μg/dL, showed that, beyond 6 months, there is not a difference between the blood lead levels in those chelated and those given placebo and no significant effect on cognitive development (6).

Another oral chelator, *d*-penicillamine, a derivative of penicillin, is given orally at a dosage of 30 mg/kg/d, with the average adult dose of about 1.0 to 1.5 g/d. It is usually used only for adults with mild or no symptoms but high lead levels. Side effects include diarrhea, renal toxicity, leukopenia and, occasionally, a rash. Penicillamine is less effective than dimercaprol or $CaNa_2EDTA$.

If renal toxicity develops as a result of antidotal therapy, fluid input should be increased to dilute the lead content of the urine. Alkalinization of the urine may also be helpful.

Chelation therapy should be continued until the lead level drops below 20 μg/dL in children and 40 μg/dL in adults. Maximum lead excretion occurs during the first 3 days of chelation therapy and falls off rapidly. After 5 days of therapy, it is unlikely that there will be further significant lead excretion without a rest period to allow lead to redistribute from tissue compartments to the blood. Hence, chelation therapy is usually limited to a 5-day course of parenteral drug, followed by a treatment-free interval of 2 to 7 days. Oral succimer therapy is usually discontinued after 19 total days of therapy. Additional courses of therapy are indicated if symptoms persist or blood lead levels remain elevated. Repeat lead levels should be monitored, initially, at least weekly. Reinstitution of therapy depends on the “rebound” in lead level. Children with lead levels below 20 μg/dL and adults with levels below 40 μg/dL do not need chelation but should be managed by preventing further

exposure by environmental and educational interventions. Follow-up evaluation and periodic monitoring are required.

The vast majority of lead-poisoned patients survive although the final neurologic outcome may not be known for many weeks or months after treatment. Patients with cerebral edema have a poor prognosis.

CRITICAL INTERVENTIONS

- Consult a poison center or lead-poisoning expert for management advice in patients with suspected or confirmed lead poisoning.
- Admit patients with lead encephalopathy and administer dimercaprol (BAL) IM followed by IV calcium disodium EDTA (calcium disodium versenate).
- Obtain blood lead levels in children with suspected exposure and arrange for close follow-up.
- Use special lead-free blood collection tubes and technique to collect specimens.

DISPOSITION

All patients with evidence of encephalopathy should be admitted. Although chelation with $CaNa_2EDTA$, penicillamine, and succimer can be done on an outpatient basis, it is advisable to admit all patients who are symptomatic. Since separation from source of lead is paramount in treating the lead-poisoned patient, admission may be the safest approach, even in the asymptomatic patient. Because blood lead levels are not immediately available at the time of initial evaluation, patients who are not acutely ill can be discharged and admitted later if blood lead confirms the suspected diagnosis.

For patients admitted for chelation the following can be considered a good guideline for discharge.

1. Blood lead levels dropped by a minimum of 50% or to <25 μg/dL.
2. Source of lead exposure documented and reexposure risk eliminated.

3. Patient/family has possession of appropriate chelating medication as needed.
4. Chelator can be administered correctly, if a child then an appropriate caregiver demonstrates the ability to administer the drug.
5. Weekly follow-up arranged to insure follow-up at least until blood lead level has stabilized < 25 μg/dL.

Further exposure to lead must be prevented with environmental and occupational investigations to determine the most likely source of lead so that it can be eliminated. Involvement of the public health department, primarily for a child with lead poisoning, is imperative. Many states have active divisions of occupational and environmental health that may be helpful in the long-term treatment of patients.

Although chelation therapy is not difficult, some of the nuances are appreciated only after treating many patients so it may be helpful to consult an experienced toxicologist or a regional poison control center.

All patients should be seen within 2 weeks of chelation therapy for repeat lead and FEP levels, because lead will be mobilized from storage sites, and blood levels will rebound after treatment. However, without continued exposure to lead, it is rare for the lead level at 2 weeks after therapy to equal or exceed the initial level.

Common Pitfalls

- Failure to consider the diagnosis of lead poisoning in patients with cognitive dysfunction, neurologic symptoms, and GI complaints.
- Failure to appreciate that elevated lead levels without coincidental elevations in FEP may be seen with recent exposures and to treat the patient with an extremely high lead level regardless of the FEP level.
- Failure to appreciate that lead poisoning is a reportable illness in many states.
- Failure to identify the source of lead and to prevent reexposure.

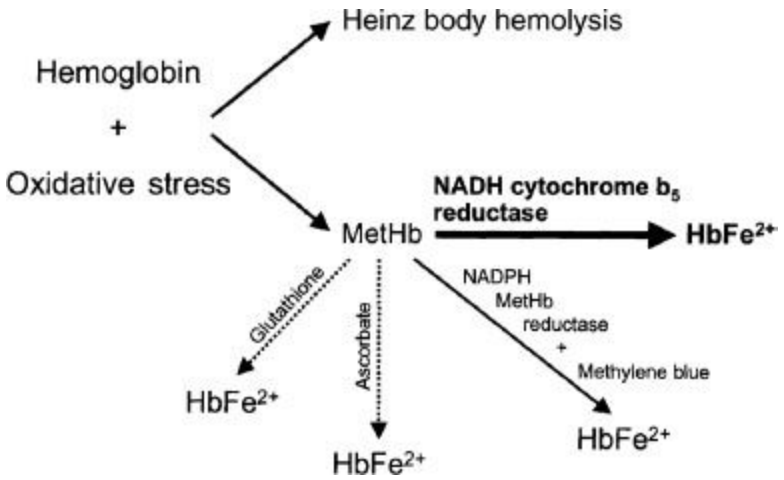
CHAPTER 335 Methemoglobinemia

David A. Tanen

Normal hemoglobin (oxyhemoglobin and deoxyhemoglobin) contains four heme groups, each with a ferrous (Fe^{2+}) ion capable of binding oxygen. Oxidative stress within the red cell produces methemoglobinemia when the iron in reduced hemoglobin is oxidized to the ferric state (Fe^{3+}). Under normal conditions, methemoglobin levels are <1% to 2% of total heme pigments. Higher fractions are termed *methemoglobinemia.* Oxidative stress within the red cell can also lead to the denaturation of red cell proteins (Heinz bodies), splenic sequestration of damaged erythrocytes (bite cells), and hemolysis.

Hemoglobin is slowly oxidized to methemoglobin under normal conditions, but the erythrocyte can catalyze the reduction of methemoglobin back to reduced hemoglobin (eFig. 335.1) by the enzyme variously known as NADH-dependent methemoglobin reductase or NADH cytochrome-b_5 reductase.



eFIGURE 335.1 Pathways of hemoglobin oxidation and methemoglobin reduction.

In normal people, enzymatic reduction of methemoglobin occurs at a rate 200- to 300-fold greater than its spontaneous formation. However, congenital deficiencies in NADH cytochrome-b_5 reductase or in cytochrome-b_5 itself can cause methemoglobinemia or can greatly predispose a person to developing methemoglobinemia. Neonates are at increased risk for developing methemoglobinemia after metabolic acidosis or oxidant stress (e.g., drugs, toxins, sepsis) because they have lower levels of NADH cytochrome-b_5 reductase and cytochrome-b_5 until they reach 4 months of age (1,2).

A second enzyme, nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, can facilitate the reduction of methemoglobin, but there is no cofactor for this enzyme. It has no role in maintaining methemoglobin levels at normal concentrations, however, exogenously administered methylene blue acts as an intermediate and greatly increases the activity of this enzyme.

People with depressed levels of erythrocytic NADPH (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency) or a congenital lack of the NADPH-dependent reducing enzyme do not normally suffer from and are not predisposed to developing methemoglobinemia. However, if these patients who are functionally G6PD deficient do develop methemoglobinemia, treatment with methylene blue would be ineffective and may even trigger massive hemolysis (3).

Exposure to a variety of agents may result in acquired methemoglobinemia (Table 335.1). Not all of the compounds are direct oxidants, so in some cases, their metabolites or oxidizing intermediates (e.g., free radicals) are responsible for producing the methemoglobin. Although infrequently encountered, the most common therapeutic agents that cause methemoglobinemia are local anesthetics, which may be injected or applied topically (e.g., infant teething gels and benzocaine sprays), metoclopramide (Reglan),

phenazopyridine (Pyridium), and diaminodiphenylsulfone (Dapsone) (4,5).

TABLE 335.1
Some Methemoglobin-Producing Agents

Acetanilide	Food Additives	Phenacetin
Amyl nitrite	Hydrazines	Phenols
Aniline dyes	Hydroxylamine	Phenylazopyridine
Arsine	Inks	Prilocaine
Benzocaine	Lidocaine	Primaquine
Bismuth sulfate	Local anesthetics	Pyridine
Chlorates	Methylene blue	Quinones
Chromates	Metoclopramide	Riluzole
Cyclophosphamide	Mushrooms	Shoe dye or polish
Dapsone	Naphthalene	Sulfonamides
Dinitrophenol	Nitrates	Sulfones
Dinitrotoluene	Nitrites	Toluidine
EMLA	Nitrobenzene	Trinitrotoluene
Flutamide	Nitroglycerin	

Many environmental exposures can lead to the induction of methemoglobinemia. Aniline and related aromatic amines are some of the most common, along with exposure to nitrates that are converted to nitrites by bacteria in the gastrointestinal (GI) tract. Fatal cases of methemoglobinemia have been reported in infants who ingested well water high in nitrites. The recreational use of inhalable nitrites that are used as sexual enhancers, such as isobutyl nitrite has also caused methemoglobinemia (6).

Compared to red oxyhemoglobin, methemoglobin may possess a characteristic “chocolate brown color.” Typically, cyanosis requires 5 g/dL blood of reduced (ferrous) hemoglobin. However, in methemoglobinemia, only 1.5 g/dL of ferric heme is needed for noticeable discoloration. Therefore, cyanosis may be seen in nonanemic patients with 10% to 20% methemoglobin. Methemoglobin cannot transport oxygen and results in a functional anemia. The presence of ferric heme groups impairs the unloading

of oxygen by oxygenated (ferrous) heme, producing a leftward shift in the oxyhemoglobin dissociation curve. The physiologic consequences of methemoglobinemia are secondary to decreased tissue oxygenation. Metabolic acidosis develops secondary to functional hypoxia.

CLINICAL PRESENTATION

Nonanemic patients with 10% to 20% methemoglobinemia usually present with unexplained cyanosis and no other symptoms. Headache, dyspnea on exertion, tachypnea, tachycardia, and mild hypertension usually are not noted until the methemoglobin levels reach 15% to 35%. Higher fractions can result in confusion, coma, seizures, apnea, ventricular dysrhythmias, bradyarrhythmias, hypotension, and lactic acidosis. Death is frequently seen with methemoglobin fractions above 70%.

Patients with underlying cardiovascular or cerebrovascular disease are more susceptible to the effects of hypoxia. Those with pre-existing anemia or with concomitant Heinz body hemolytic anemia suffer greater toxicity at a given methemoglobin level, because the remaining functional hemoglobin concentration is lower. Also, cyanosis may not be apparent in the anemic patient because a greater percentage of methemoglobin would be needed to reach the 1.5 g/dL threshold of cyanosis as compared to the nonanemic patient. Hence, anemic patients can suffer from significant methemoglobinemia without exhibiting cyanosis.

The cyanosis of methemoglobinemia is refractory to oxygen. The arterial $PO_{2,}$ which measures dissolved oxygen in plasma, is actually normal or elevated and can be measured accurately by a co-oximeter. Pulse oximetry measurements, however, are inaccurate in the presence of methemoglobin, which falsely lowers the oxygen saturation reading. Metabolic acidosis may be present in severe cases. Venous blood may have a brown hue. A low hemoglobin, bite cells on peripheral blood smear, Heinz bodies with this stain, and increased serum haptoglobin and pink plasma from hemoglobinemia occur in severe cases of hemolysis. The electrocardiogram (ECG)

may reveal signs of tissue hypoxia such as tachycardia, bradycardia, ventricular dysrhythmias, and myocardial ischemia.

DIFFERENTIAL DIAGNOSIS

Unlike cyanosis from hypoxia, the cyanosis of methemoglobinemia is accompanied by a normal PO_2 on blood gas analysis which does not increase with supplemental oxygen. Arterial blood gas reveals a normal percentage of oxyhemoglobin (percentage saturation) because most blood gas instruments do not directly measure oxyhemoglobin fractions but, rather, calculate what the percentage hemoglobin saturation should be based on the dissolved oxygen tension. These calculations assume the absence of methemoglobin, carboxyhemoglobin, and sulfhemoglobin and assume there is no shift in the dissociation curve from changes in erythrocytic 2,3-diphosphoglycerate concentrations (5). A co-oximeter is required to directly measure and report the true percentage saturation, the total hemoglobin concentration, and percentages of oxyhemoglobin, methemoglobin, and carboxyhemoglobin. Sulfhemoglobin is usually recognized as methemoglobin by these instruments. The difference between the percentage of theoretical hemoglobin saturation calculated by the blood gas analyzer and the actual saturation measured by the co-oximeter is called the *oxygen saturation gap.* A large oxygen saturation gap in arterial blood is almost always as a result of carboxyhemoglobin or methemoglobin. To interpret blood gas reports accurately, the emergency physician must know whether reported percentage saturations on arterial blood gas samples are determined by co-oximetry.

Most traditional pulse oximeters (e.g., ear or finger oximeters) measure only oxyhemoglobin and deoxyhemoglobin and cannot account for methemoglobin or carboxyhemoglobin. As methemoglobin rises, the pulse oximetry reading approaches 84%. Therefore, a pulse oximeter can report a falsely low hemoglobin oxygen saturation in the presence of methemoglobinemia or carboxyhemoglobinemia (7). Recently, noninvasive pulse oximetry units have been developed that can also measure methemoglobin

and carboxyhemoglobin thereby enabling the clinician to rapidly identify these conditions (8).

A peculiar and poorly characterized cyanosis may also be seen in some cases of hydrogen sulfide. Sulfhemoglobinemia, a rare cause of cyanosis, causes noticeable discoloration at only 0.5 g/dL blood and can produce a saturation gap with a normal arterial PO_2. Most co-oximeters measure sulfhemoglobin as methemoglobin. Fortunately, sulfhemoglobin is rarely (if ever) severe enough to cause life-threatening symptoms. Generalized bluish discoloration from excessive administration of methylene blue may also be confused with cyanosis (4). Other unusual causes of blue skin coloring mistaken for cyanosis include dye from tight wet clothing that leaches onto the skin.

ED EVALUATION

A careful history should be taken from the patient and family regarding medications, occupational exposures to chemicals, family history of methemoglobinemia, recreational drug use and, in the case of children, any substances in the house that could have been ingested. The physical examination should focus on vital signs, skin color, and any evidence of cerebral or myocardial hypoxia. At the bedside, a drop of the patient's blood can be placed on filter paper and allowed to dry. Blood that appears obviously brown, predicts a level of at least 15% methemoglobin, assuming a normal total hemoglobin concentration. A formal color chart for comparison has been developed to reliably predict the methemoglobin concentration (9).

KEY TESTING

- If available, specialized noninvasive pulse oximetry can assess the degree of methemoglobinemia at the bedside.
- Venous blood for co-oximetry for determination of the methemoglobin fraction.
- Bedside color comparison of brown versus red blood.

- Complete blood count, especially hemoglobin to guide methylene blue dosage.
- Serum electrolytes, blood urea nitrogen, creatinine, and glucose do not routinely assist in the diagnosis but can identify comorbidities.
- Electrocardiogram for suspicion of hypoxic cardiac stress.
- Heinz body preparation, haptoglobin, plasma-free hemoglobin concentrations. and urinalysis if hemolysis is suspected.

ED MANAGEMENT

Patients with methemoglobinemia should be placed on oxygen to maximize the oxygen delivery of the residual normal hemoglobin and oxygen dissolved in the plasma. Intravenous access should be established, and the patient should be placed on a cardiac monitor.

Most patients with mild methemoglobinemia (<30%) are blue but asymptomatic and do not require treatment (1,2). Once exposure to the offending agent is terminated, methemoglobin levels usually return to normal within 12 to 36 hours. Patients with symptoms unrelieved by oxygen, with methemoglobin fractions above 30%, ECG changes, or a metabolic acidosis should receive antidotal therapy with methylene blue, provided there is no history of G6PD deficiency. Methylene blue is available as a 1% solution (10 mg/mL) and should be given intravenously over 3 to 5 minutes at an initial dose of 2 mg/kg (0.2 mL/kg of a 1% solution) (1,2). A dramatic response with resolution of cyanosis usually occurs within 15 minutes. If the patient is seriously symptomatic and no response is noted within 15 minutes or if the patient remains moderately symptomatic after 15 to 30 minutes, repeat doses of 1 mg/kg (0.1 mL/kg of 1% solution) can be given. If methemoglobin levels are readily available, they should be performed before repeat doses of methylene blue are given, because large doses of methylene blue themselves might cause oxidation if given too rapidly and produce methemoglobinemia and can cause discoloration of skin. The total dose of methylene blue during the first 2 to 3 hours should not exceed 5 to 7 mg/kg (1,2). Patients with anemia and lower total

hemoglobin should receive correspondingly lower doses of methylene blue.

Adverse effects of methylene blue include dysuria, substernal chest pain, and anxiety. Urine frequently turns blue and then green as the drug is excreted. Single doses of methylene blue as low as 5 mg/kg has been shown to induce methemoglobinemia in animals (3).

Methylene blue is contraindicated in patients with G6PD deficiency. These patients have low erythrocytic NADPH concentrations, making augmentation of the NADPH-dependent, methemoglobin-reducing enzyme by methylene blue impossible. More important, methylene blue may trigger massive hemolysis in such patients, further compromising oxygen delivery to tissues (3). About 15% of African American males are thought to be deficient in G6PD; men and women of Mediterranean ancestry also have an increased incidence of this enzyme deficiency.

As soon as time allows, GI and skin decontamination should be performed to limit continued absorption after acute dermal exposures to chemicals or after intentional ingestions of toxic agents. Dermal decontamination can be performed with a triple wash (water rinse, soap scrub, water rinse). If the drug or chemical causing methemoglobinemia cannot be readily eliminated from the body (e.g., dapsone), methemoglobinemia may continually recur for hours or days despite successful initial treatment with methylene blue. In this instance, serial measurements of methemoglobin levels are required, and a constant intravenous infusion of methylene blue at a rate of 0.1 mg/kg/hr has been used to maintain methemoglobin concentrations at a safe level (4). Repeated oral doses of activated charcoal may also enhance the elimination of dapsone. High-dose IV cimetidine has been shown to decrease dapsone-induced methemoglobin production. Renal failure is a relative contraindication to using a constant infusion or frequently repeated doses of methylene blue, because the drug is primarily renally excreted.

Treatment with hyperbaric oxygen (HBO) or exchange transfusions should be considered for patients with G6PD deficiency

or for those who do not respond satisfactorily to methylene blue. HBO can provide enough dissolved oxygen to support life in the presence of severe methemoglobinemia.

Symptomatic hemolytic anemia may require blood transfusions. Because massive hemolysis may cause hyperkalemia and acute renal failure, efforts should be made to maintain a good rate of urine flow.

Ascorbic acid also reduces methemoglobin to hemoglobin (nonenzymatically). A dose of 0.5 to 1.0 g ascorbic acid every 6 hours may be given intravenously or orally in conjunction with methylene blue. However, ascorbic acid works too slowly to be useful in the treatment of acute, acquired methemoglobinemia (1). Although *N*-acetylcysteine has been proposed as a possible adjunct, it did not reduce elevated methemoglobin levels in a human model of methemoglobinemia (10).

CRITICAL INTERVENTIONS

- Administer 100% oxygen to patients with suspected or diagnosed methemoglobinemia.
- Measure methemoglobin levels.
- Obtain Heinz body blood stain, serum haptoglobin, and plasma-free hemoglobin concentration in patients with a low hemoglobin.
- Administer methylene blue to patients with signs of cardiac ischemia, dyspnea, metabolic acidosis, or methemoglobin levels $>30\%$.

DISPOSITION

Patients with methemoglobinemia should be admitted after emergency department (ED) evaluation and management. Patients are best managed at a facility in which methemoglobin concentrations can be measured easily and quickly. If transfer is necessary, advanced life-support services and a supply of methylene blue should be available enroute. In the case of an accidental or intentional poisoning, the physician must evaluate and treat other

toxic effects of methemoglobin-producing agents. All patients who receive methylene blue should be observed for recurrence of symptomatic methemoglobinemia and for adverse effects such as hemolysis.

An asymptomatic and otherwise healthy patient who has been cyanotic for several days does not require admission if the total hemoglobin concentration is normal, the methemoglobin level is below 20%, exposure to the offending agent is terminated, and reliable follow-up is available. Methemoglobin concentrations will return to normal in these patients as the offending drug is cleared from the body. A conservative approach would be to admit all young children and elderly patients for observation, serial methemoglobin concentrations and, when indicated, serial ECGs.

Any patient who unexpectedly develops methemoglobinemia should be referred to a hematologist for evaluation of possible NADH cytochrome-b5 reductase deficiency. Any patient with methemoglobinemia that is unresponsive to treatment with methylene blue should be evaluated, after full recovery, for G6PD deficiency and the much less common, NADPH methemoglobin reductase deficiency.

Common Pitfalls

- Failure to consider the diagnosis of methemoglobinemia in patients with cyanosis unresponsive to oxygen.
- Failure to appreciate that a normal arterial PO_2 and a normal oxygen saturation calculated from arterial blood gases does not rule out methemoglobinemia.
- Failure to appreciate that resolution of cyanosis in a patient with methemoglobinemia may be as a result of accompanying hemolysis, with actual worsening of oxygen delivery to tissues.
- Failure to appreciate that methylene blue is contraindicated in patients with G6PD deficiency.

CHAPTER 336

Irritant Gases and Other Toxic Inhalants

Kenneth D. Katz and Robert D. Cannon

Toxic inhalants can be (1) simple asphyxiants, nontoxic gases which displace oxygen in the atmosphere (not discussed in this book), (2) systemic asphyxiants (see Chapters 327, 329, and 332) or (3) irritant gases, discussed in this chapter, and (4) gases with other systemic effects, also discussed in this chapter. Irritant gases can cause injury anywhere from the oral mucosa to the pulmonary parenchyma and internal organs. The deposition and absorption of a gas or vapor in the respiratory tract are primarily governed by its water solubility. Highly water-soluble airway irritants such as chlorine and hydrochloric acid are quickly absorbed in the upper airways and usually cause mucous membrane and upper airway irritation. In contrast, less water-soluble chemicals such as phosgene tend to reach the lower airways and alveolar membrane, causing bronchospasm and delayed pulmonary edema (1). In addition, specific agents are responsible for clinically significant systemic toxicity and hypersensitivity responses with which the emergency physician should be familiar.

CLINICAL PRESENTATION

Inhalants with Immediate-Onset Symptoms

Agents that are intermediately or highly water-soluble generally produce immediate symptoms of mucous membrane irritation. The most commonly encountered agents in this category are chlorine

gas, chloramines, and ammonia. Less commonly encountered agents include sulfur dioxide (SO_2), formaldehyde, and chloropicrin.

Chlorine, a gas with intermediate water solubility, became infamous as a chemical warfare agent in World War I. It is heavy, dense, and greenish yellow in color. Exposure to chlorine gas may occur in several different settings. Industrially, it is used for water purification, as well as in textile and paper bleaching processes (2). Mixing an acid (typically found in toilet bowl cleaners) with bleach liberates chlorine gas in household exposures, which occurs fairly frequently (3). Finally, exposure to concentrated chlorine gas often occurs from accidents and malfunctions in pool chlorination systems (4).

Chlorine-induced injury results from its reaction with water on mucous membranes and the respiratory tract, forming hydrochloric acid (HCl), and hypochlorous acid (HOCl), which cause to tissue injury. Furthermore, HOCl degrades to HCl and oxygen-free radicals, which leads to oxidative cellular damage (2).

The clinical effects of chlorine gas exposure depend upon the concentration and duration of exposure. Individuals with brief low-dose household exposure most commonly complain of cough followed by shortness of breath and throat irritation. In the vast majority of patients symptoms resolve within about six hours (3). As the concentration and duration of exposure increase, the degree of mucous membrane and airway injury increases, which ultimately can lead to acute lung injury, adult respiratory distress syndrome, and even death with massive exposures (2).

Chloramines are produced when bleach is mixed with ammonia. Upon contact with mucous membranes and the respiratory tract, they degrade to ammonia, HOCl, and oxygen-free radicals, which cause an injury pattern similar to chlorine gas. Although acute lung injury has occurred with household exposures, the vast majority of patients experience resolution of their symptoms within several hours from exposure (5,6).

Ammonia is a highly water-soluble gas that has a characteristic pungent odor. It is used as a component of agricultural fertilizer, in

the manufacturing of plastics and explosives, and as a refrigerant and cleaning agent. Upon contact with water, it forms ammonium hydroxide, which causes a rapid and severe upper airway injury. Ammonia's strong odor and the rapid mucous membrane irritation it causes usually prevent ongoing exposure and further injury. However, individuals exposed to highly concentrated gas or those with prolonged exposure may develop lower respiratory tract injury and severe acute lung injury.

Sulfur dioxide (SO_2) is another highly water-soluble gas that has many industrial and occupational uses. It is a by-product in the smelting and oil refinery industries. It is also used as a preservative for fruits and vegetables, as a disinfectant in wineries and breweries, and as a bleaching agent in the textile and paper industries. In the presence of water, SO_2 is readily converted to sulfurous acid (H_2SO_3), which is largely responsible for producing the mucosal injury. Due to its characteristic pungent "burning match" odor, potential victims tend to remove themselves from exposure before severe injury can develop, and effects are therefore most often limited to upper airway and mucous membrane irritation. Higher concentrations, however, have been shown to cause morphologic changes consistent with acute lung injury, and, indeed, individuals with large or prolonged exposure can develop acute pulmonary edema and die within hours of exposure (7).

Pure formaldehyde is a gas at room temperature. The majority of formaldehyde produced in the United States is used for plastics and resin manufacturing. It is highly water-soluble and extremely irritating, primarily to upper respiratory mucous membranes.

Chloropicrin is a fumigant that has been used for cereals and grains. Because it is a highly potent irritant and lacrimator, it is also added to structural fumigants as a warning agent. It causes mainly mucous membrane irritation, but lung injury may occur with a high dose or prolonged exposure.

Inhalants with Delayed-Onset Symptoms

In contrast to the agents with high and intermediate water solubility, gases with low water solubility tend not to cause immediate mucous membrane irritation. This lack of symptoms may lead to prolonged exposure. Once poorly water-soluble gases are inhaled into the alveoli, their dissolution into the epithelial fluid occurs slowly over several hours, producing a delayed-onset pulmonary edema. Two important gases in this category are phosgene (carbonyl chloride) and nitrogen dioxide (NO_2).

Phosgene is a colorless gas with a smell often described as that of freshly mown hay. It was used as a chemical warfare agent in World War I and was estimated to cause more than 80% of all poisonous gas fatalities. Today, phosgene is used as an intermediate in the production of isocyanates, polyurethanes, pharmaceuticals, dyestuffs, and carbamate pesticides. In addition, it is formed upon the combustion of chlorinated organic compounds (8).

Phosgene causes injury by two mechanisms: acylation and hydrolysis to hydrochloric acid. As phosgene acylates sulfhydryl, hydroxyl, and amino groups, it disrupts the cell membrane and various cellular enzymes which ultimately lead to pulmonary cellular death. Second, upon contact with water, phosgene is slowly hydrolyzed to hydrochloric acid (HCl), which directly causes mucosal and pulmonary injury.

Unless there is a large exposure to concentrated gas, phosgene produces little to no immediate mucous membrane irritation. Although pulmonary injury may occur within an hour of exposure, the development of clinical symptoms may be delayed for 15 to 30 hours. The chest x-ray may appear normal or show only very subtle changes initially, but frank pulmonary edema may develop over 24 hours (8).

Nitrogen dioxide (NO_2) is a reddish-brown gas with a pungent odor and may be encountered in several different scenarios. NO_2 can form in grain silos as “silo gas” when the silage nitrates are fermented into nitrites, which subsequently combine with organic acids to form nitrous acid. Nitrous acid decomposes to water and other nitrogen oxides, which cause silo-filler’s disease (9). Another

source of exposure is through the exhaust of propane-powered ice cleaning machines in poorly ventilated ice skating rinks. Finally, nitrogen oxides may be generated by welding and as a by-product of the combustion of nitrocellulose, which is a major component of radiographic film.

Although NO_2 can directly oxidize cell membranes, it also forms reactive nitrogen species, particularly perioxynitrite ($ONOO^-$). These reactive species cause inflammation and damage to bronchiolar and alveolar type I and II epithelial cells. In addition to generating reactive nitrogen species, NO_2 forms nitric acid upon contact with respiratory tract water, which further contributes to pulmonary injury (10). Due to its poor water solubility, NO_2 often causes little or no immediate mucous membrane irritation. The result is a relatively asymptomatic patient with a normal chest x-ray, who may go on to develop pulmonary edema and clinical symptoms within 24 hours of exposure; at extremely high concentration, however, it can still cause sudden loss of consciousness.

Miscellaneous Irritants

Isocyanates are used in the production of urethane foams for insulation, packaging, and the sealing of electrical equipment. They are also used in many paints and finishes. Of the isocyanates, methyl isocyanate (MIC) is the most potent respiratory tract irritant, and its inadvertent release in 1984 in Bhopal, India, was responsible for more than 2,000 deaths. Today, MIC has largely been replaced by methylene diphenyl diisocyanate (MDI) and toluene diisocyanate (TDI). MDI is relatively safe because of its low volatility. However, TDI is volatile and can be easily inhaled to produce acute irritation of the mucous membranes and respiratory tract. It can also cause sensitization leading to the development of occupational asthma.

Pulmonary Inhalants with Systemic Toxicity

Arsine gas (AsH_3, arsenous hydride) is colorless gas with a garlic odor, generated when arsenic-containing materials contact water or acid (11). Common industrial processes that result in arsine formation include metal refining, smelting, and computer and fiberoptic chip manufacture. Arsine is generally a nonirritating gas, and exposures <0.5 ppm may not be readily apparent (12). Signs and symptoms may develop within 2 to 24 hours of exposure and include: nausea, vomiting, abdominal pain, diarrhea, dizziness, and weakness (12). The most feared complication of arsine exposure is intravascular hemolysis, evidenced by "black" urine, jaundice, and acute renal failure secondary to both direct arsine toxicity and heme pigment-associated tubular necrosis. The classic presentation of arsine poisoning is the clinical triad of jaundice, abdominal pain, and hematuria. Other reported signs and symptoms include pulmonary edema, skin "bronzing," myalgias, and delayed-onset peripheral neuropathy (13). Arsine-induced hemolysis may be related to disruption of red blood cell membrane ion gradients causing membrane instability and also direct heme release (12). Blood or spot urine arsenic measurements can aid in the initial diagnosis and can be followed up during treatment. Removal of the arsine hemoglobin complex and red blood cell fragments via early plasma exchange transfusion has been associated with clinical improvement and reduction in blood and urine arsenic levels. With the use of hybrid blood purification therapy (plasma exchange and continuous venovenous hemofiltration), 10 of 11 patients survived severe, acute arsine toxicity; however, there was no control group (11). Chelation therapy, as used for arsenic, has not been effective in arsine poisoning.

Ethylene oxide is a colorless gas with an ether-like odor commonly used as a sterilizing agent in hospitals. Mucosal irritation, dermal burns, nausea, vomiting, chest tightness, cough, dyspnea, loss of consciousness, and seizures have all been reported after acute ethylene oxide exposure. After chronic exposure, ethylene oxide has been associated with contact dermatitis and peripheral neuropathy (14). It has also been associated with a possible increased risk for

miscarriage and cancer. Treatment is removal from the source and supportive.

Phosphine gas (PH_3) is generated from the contact of aluminum phosphide and water. Aluminum phosphide is a solid fumigant pesticide used to preserve grain. Unintentional exposure occurs from inhalation of or dermal exposure to phosphine generated from fumigated grains. Lemoine et al. (15) recently reported a rare and unfortunate case of inhalation with two fatalities after an entire family was accidentally poisoned when aluminum phosphide pellets were used as a rodenticide outside the home. Intentional phosphine poisoning, by ingestion of solid aluminum phosphide tablets, or "Rice tablets", that react with gastrointestinal mucosa to form phosphine, is a common form of suicide in countries such as India (16). Signs and symptoms include initial severe vomiting followed by coma, seizures, metabolic acidosis, hypotension, and cardiovascular collapse. Other reported clinical manifestations include: cardiac arrhythmias, pulmonary edema, acute respiratory distress syndrome, hemolysis, methemoglobinemia, disseminated intravascular coagulation, acute tubular necrosis, hepatitis, and pancreatitis. Survivors of ingestion may develop esophageal strictures. A characteristic fishy or garlic odor is commonly described with phosphine exposure to air and may be a helpful clue to diagnosis. Although "off gassing" of phosphine from patients' vomitus or expired breath and causing toxicity in rescuers has been reported, "spontaneous ignition" has been reported Phosphine toxicity is believed to occur from free radical oxidant damage and inhibition of mitochondrial cytochrome c oxidase (16). Treatment is immediate removal from the source of exposure, including contaminated clothing, and skin washing with water in cases of dermal exposure and immediate cardiopulmonary resuscitation. There is no antidote for phosphine poisoning. Elevated blood and tissue phosphine levels have been reported after exposure (17). A bedside test using silver nitrate-impregnated paper on breath or heated gastric contents may provide a more rapid diagnosis. Treatment with immediate gastric lavage after ingestion, oral

coconut oil, magnesium, trimetazidine and, recently, gastric ventilation, have all been reported, but none has been validated. Sodium bicarbonate should be given to correct metabolic acidosis. Mortality has been reported as high as 60% (16). Recently, a prospective, randomized, controlled study of adding N-acetylcysteine (NAC) to supportive care demonstrated reduced biomarkers of oxidative stress, a decreased need for intubation, shorter length of ICU stay, and lower mortality rates in those who received NAC compared to controls (18).

Methyl bromide is a halogenated hydrocarbon used until the 1950s as a fire extinguisher but now employed primarily as a fumigant. It is a colorless and odorless gas even at high concentrations and is readily absorbed by the lungs and skin. Acute exposure is associated with early gastrointestinal upset, dizziness, and headache, which can be followed by progressive neurologic deterioration, including coma, myoclonus, seizures, and status epilepticus. Myocardial sensitization and ventricular arrhythmias have been reported. Pulmonary edema and both liver and renal insufficiency have also been associated with methyl bromide toxicity. Peripheral neuropathy and persistent psychiatric disturbances have been reported after large exposures (19). The mechanisms of methyl bromide toxicity may include (1) methylation of sulfur-containing enzymes similar to other metals, (2) glutathione depletion, and (3) free radical formation (19). Plasma bromide levels can help confirm exposure but may not predict toxicity. More immediate diagnostic clues are a falsely elevated serum chloride and low anion gap (19). Treatment is removal from the source and supportive care, with aggressive control of seizures with benzodiazepines. Catecholamines should be avoided in the presence of ventricular arrhythmias. Chelation, N-acetylcysteine, and hemodialysis are potential treatments.

Ethylene dibromide (1,2-dibromomethane) is a colorless liquid with a chloroform odor sold in 3-mL ampules. It was common fumigant in the United States until 1984, when its use was restricted; however, it is still used in countries such as India where it remains a common source of poisoning. Toxicity has been

reported with ingestion, inhalation, and dermal exposure; death has been reported with ingestion of as little as half an ampule (20). Clinical signs and symptoms include initial gastrointestinal and pulmonary disturbances, progressing to metabolic acidosis, liver and renal failure, and cardiovascular collapse (20). There is no antidote, and treatment is supportive. Favorable outcomes are associated with arrival to the hospital within six hours after exposure and normal hemodynamics at presentation.

Sulfuryl fluoride (Vikane) is a colorless, odorless fumigant used with the warning agent chloropicrin. Mucous membrane irritation and pulmonary edema occur with exposure to the warning lacrimator, chloropicrin. Hypocalcemia, hyperkalemia, metabolic acidosis, seizures, and ventricular arrhythmias occur with systemic fluoride toxicity. Treatment includes removal from the source, control of seizures, sodium bicarbonate for metabolic acidosis, and aggressive electrolyte supplementation.

Polymer fume fever is self-limited manifestation of exposure to polytetrafluoroethylene (Teflon) pyrolysis products. Typically, heating of contaminated products, such as cigarettes or hairspray, causes inhalation of pyrolyzed fluorinated polymer fumes and development of fever, cough, and dyspnea, but a normal chest radiograph. Rarely, pulmonary consolidation can occur with prolonged exposure or higher temperatures, Resolution occurs over 24 to 48 hours and is treated supportively with bronchodilators, antipyretics, adequate ventilation, and education on avoiding future exposure (21).

Metal fume fever (“Monday morning fever,” “Galvanizers poisoning,” “smelter’s chill”) is a self-limited respiratory illness secondary to metal oxide fume exposure, typically zinc. Similar to polymer fume fever, patients present with abrupt onset of fever, cough, dyspnea, myalgia, headache, and metallic taste within 48 hours of exposure with a similar duration. Chest radiographs are typically normal, and treatment is supportive. Metal levels are not elevated. Transient tolerance to oxide fumes is thought to occur, thus causing “Monday morning fever” with improvement over the weekend and recurrent symptoms upon re-exposure at the beginning

of the next work week (22). Repeated episodes should prompt the clinician to address proper workplace protective measures.

DIFFERENTIAL DIAGNOSIS

Similar clinical presentations may be caused by more common cardiac, allergic, infectious, or intrinsic lung diseases so these poisonings are easy to overlook if a history of exposure is not obtained. Entities such as metal or polymer fume fever resemble influenza-like illness, but are generally very rapid in onset and resolve relatively quickly compared to infectious diseases. As highly water-soluble gases generally cause acute mucous membrane and upper airway irritation, prompt symptom resolution after removal from the exposure can help distinguish inhalant toxicity from other causes. Less water-soluble agents may cause delayed pulmonary toxicity and may mimic other causes of noncardiogenic pulmonary edema, such as opioid or salicylate poisoning. Unusual toxicities, such as arsine-induced hemolysis, could present similarly to other causes of intravascular hemolysis such as paroxysmal nocturnal hemoglobinuria. A detailed history from the patient, scene responders, family, or coworkers is extremely helpful in differentiating an occupational exposure from an intrinsic medical cause. Unique odors may potentially be helpful, especially in cases of phosgene, phosphine, or arsine poisoning, for example.

ED EVALUATION

Signs and symptoms after a highly water-soluble gas exposure are sudden and easily noted, and correlated to a chemical exposure, but symptoms from other inhaled exposures may be nonspecific, delayed, progressive, and unexpected, making the diagnosis difficult to suspect. An accurate exposure history and review of medical history are paramount.

The emergency department (ED) evaluation includes germane medical history and details of the presenting illness, such as the nature, timing, and severity of symptoms and antecedent recreational or occupational activity. Also, if several patients present

with similar complaints, a common exposure to an irritant gas may be involved. The Material Safety Data Sheet (MSDS) for chemicals at the worksite should always be requested from worksites and carefully reviewed.

Vital sign abnormalities should be noted, especially decreased oxygen saturation, tachypnea, or fever. The physical examination should focus on any mucous membrane or skin involvement and abnormal cardiopulmonary findings. A peak flow measurement can monitor bronchospasm and a chest radiograph should be performed in patients with significant respiratory distress or hypoxemia, especially when pulmonary edema is suspected. Routine laboratory testing is generally not needed unless it is to exclude other disorders. However, in cases of suspected arsine toxicity, diagnostic testing should include urine or blood arsenic levels, complete blood count, renal function, indirect bilirubin, haptoglobin, lactate dehydrogenase, and urinalysis. Serum chemistries and ECG should be included in cases of sulfuryl fluoride exposure. Likewise, for phosphine and bromide, appropriate blood samples may help confirm exposure. A falsely elevated serum chloride and low anion gap may provide evidence of bromide exposure. Also, a bedside silver nitrate paper test on breath or gastric contents can help to quickly diagnose phosphine exposure.

KEY TESTING

- Peak flow measurement and CXR as needed for symptoms
- Routine laboratories are generally not helpful
- Test for hemolysis after arsine poisoning

ED MANAGEMENT

Removal from the exposure, rapid decontamination, and supportive care are the mainstays of prehospital treatment. A rescuer should never enter an area in which a toxic inhalant is potentially present without having adequate protection such as the self-contained breathing apparatus used by fire-fighters. Along with the provision of supplemental oxygen, thorough flushing of irritated surfaces with

water may be required. For inhalation only, without liquid condensation, no decontamination is necessary. If liquid toxin is on clothing or skin, simple decontamination maneuvers include removal and containment of contaminated clothing and washing of skin with soap and water.

Respiratory therapy is primarily supportive and should include humidified oxygen, bronchodilators for clinical evidence of bronchospasm, and either noninvasive ventilation or endotracheal intubation with positive end-expiratory pressure (PEEP) as clinically indicated for more severe lung injury or pulmonary edema. In pigs exposed to chlorine gas, inhaled budesonide and intravenous betamethasone improved oxygenation, pulmonary vascular resistance, and airway pressures but because of a lack of controlled clinical trials and unclear indications for their use in humans, their use cannot be recommended as routine management (23). Corticosteroid administration may be considered in severe cases of lung injury or based on local practice patterns. Sodium bicarbonate nebulization for chlorine gas inhalation is also controversial. Although case reports suggest a possible benefit, prospective study of individuals with chlorine gas inhalation has failed to demonstrate a clinically significant benefit.

Exchange transfusion may be needed for arsine-induced hemolysis. Sodium bicarbonate administration and NAC therapy should be considered for patients with phosphine toxicity to correct metabolic acidosis and oxidant stress, respectively. Supportive therapies may be needed, such as benzodiazepines or barbiturates for seizures, and hemodialysis for renal failure. Aggressive electrolyte and acid base management may be needed in patients exposed to sulfuryl fluoride. Identification of the sources of and reasons for exposure, especially in industrial settings, is critical during ED evaluation to limit potential future poisoning.

CRITICAL INTERVENTIONS

- Measure oxygen saturation in all patients with irritant gas exposure.

- Administer oxygen and bronchodilators to patients with cough, dyspnea, or wheezing; consider corticosteroid therapy in those with severe or persistent symptoms.
- Use PEEP or intubate to provide and controlled ventilation in patients with pulmonary edema or severe respiratory distress that is unresponsive to supportive care.
- For arsine toxicity, consider early institution of plasma exchange.

DISPOSITION

The decision to admit or discharge depends primarily on the severity and progression of clinical and laboratory manifestations. Patients exposed to agents that do not cause delayed pulmonary edema and who are or become asymptomatic after six hours of ED observation and treatment may be discharged, with follow-up as necessary. Those with moderate, severe, or worsening symptoms, hypoxemia, or pulmonary edema should be admitted to the appropriate hospital unit. If delayed toxicity is possible, patients who have even minimal initial symptoms should be admitted and observed for 24 hours. When possible, the MSDS should be reviewed, and the regional poison center and medical toxicologist should be consulted to help guide treatment and disposition. Patients who are discharged should be instructed to return if symptoms recur or worsen. Discharged patients should also be advised to avoid circumstances that resulted in exposure.

Common Pitfalls

- Failure to adequately decontaminate patients and to use proper protective equipment for patients with volatile liquid and gas exposure.
- Decontaminating patients who have had isolated gas exposure without risk of secondary contamination.
- Failure to take an adequate environmental or occupational exposure history.
- Failure to consider the possibility of delayed or systemic poisoning after gas exposure.

- Failure to obtain the most information possible from MSDS, regional poison center, the manufacturer, and other sources for further information regarding specific agent.
- Failure to instruct patients to avoid circumstances that led to exposure.

CHAPTER 337
Smoke Inhalation

Heather Long

Smoke inhalation is the number one cause of death from fire and is the most common cause of acute inhalation injury seen in the emergency department (ED). Furthermore, burn patients with smoke inhalation have much greater morbidity and mortality, with increased rates of pneumonia, infection, sepsis, and increased length of hospital stay. The overall mortality rate from burns averages 13.9% but, among those with concomitant smoke inhalation injury, mortality rises to 27.6% (1).

Smoke is a mixture of heated air, gases, fumes, aerosols, vapors, and solid and liquid particles in suspension. Smoke toxicity depends on the composition of the fuel, the availability of oxygen, the completeness of combustion, and the heat intensity. Even within the same building, smoke composition can vary considerably with duration of the fire and location. Toxic combustion products (TCPs) from naturally occurring materials and synthetic polymers in the modern environment contribute to smoke toxicity (Table 337.1).

TABLE 337.1
Toxic Products of Combustion

Product of Combustion	Common Sources
Acids/aldehydes	Cellulose acetate (film), cotton, paper polystyrene, polyvinyl acetate, wood
Acrolein	Acrilan (carpet), acrylic, celluloid, cellulosics, polyolefins
Ammonia	Nylon, resins (melamine, phenolic), silk, wood
Carbon monoxide/dioxide	All organic material
Chlorine/hydrochloric acid/ phosgene	Chlorinated acrylics and hydrocarbons (fire extinguishers and retardants)
Cyanide/hydrogen cyanide	Acrylonitriles, nylon, paper, polyurethane, nitrocellulose (film), resins, silk, wool
Halogen acids and gases (Br, F)	Halogenated hydrocarbons, films, resins, flame retardants, and extinguishers
Isocyanates	Polyurethane
Nitrogen oxides	Celluloid, cellulose nitrate fabrics, paper, petroleum products, wood
Styrene	Polystyrene
Sulfur oxides/hydrogen sulfide	Hair, hides, meat, petroleum products, rubber, wool

TCPs like other inhaled toxins (Chapter 336, “Inhaled Toxins”) are categorized as simple asphyxiants, chemical asphyxiants, or irritant toxins (Table 337.2). Simple asphyxiants displace oxygen from the ambient environment causing suffocation but they generally have no inherent toxicity. The process of combustion itself depletes oxygen from the environment as well.

TABLE 337.2
Toxic Combustion Products

Simple Asphyxiants	Chemical Asphyxiants	Irritants
Carbon dioxide	Carbon monoxide	Highly water-soluble
Helium	Hydrogen cyanide	Acrolein
Methane	Hydrogen sulfide	Ammonia
Natural gas	Oxides of nitrogen	Formaldehyde
Nitrogen		Hydrogen chloride
Noble gases		Sulfur dioxide
Oxygen-deprived environment		Intermediate water solubility
		Chlorine
Propane		Isocyanates
		Poorly water-soluble
		Oxides of nitrogen
		Phosgene

Chemical asphyxiants inhibit cellular respiration by inhibiting mitochondrial electron transport or by impairing oxygen delivery. Agents inhibiting mitochondrial electron transport include carbon monoxide (Chapter 327), hydrogen cyanide (Chapter 329), and hydrogen sulfide (Chapter 332). Carbon monoxide and oxides of nitrogen, by inducing carboxyhemoglobin (COHgb) formation or methemoglobinemia (see Chapter 335), respectively, impair oxygen transport and delivery to tissues.

Carbon monoxide, produced by the incomplete combustion of any carbon-containing compound such as wood, charcoal, and propane, is still the major toxicant in modern fires. However, COHgb fractions in smoke inhalation deaths are often $<50\%$. An oxygen-poor environment combined with even sub-lethal levels of carbon monoxide significantly reduces the time to death. Blood ethanol concentrations correlate strongly with the COHgb fraction, suggesting that ethanol intoxication impairs the ability to recognize and escape danger, consequently prolonging smoke exposure.

Cyanide is produced from the combustion of nitrogen-containing products such as wool, silk, nylon, plastics, polyurethane, nitrocellulose, and synthetic rubber. Cyanide is present in appreciable amounts in air samples from fires and in blood from fire victims and is thought to have an additive, even synergistic effect,

on smoke toxicity. Cyanide levels >0.1 mg/L are considered abnormal.

Combustion of nitrogen-containing materials generates oxides of nitrogen. These oxides are capable of inducing methemoglobinemia and may also directly oxidize cells of the respiratory tract or generate free radicals that induce delayed damage to the respiratory epithelium. Methemoglobinemia is rarely reported in smoke inhalation victims. Combustion of nitrocellulose, a major component of radiographic film, caused 125 deaths as a result of cyanide and nitrogen dioxide poisoning in the 1929 fire in the Cleveland Clinic radiology department (2).

Irritant toxins are a varied group of chemically reactive compounds that ultimately exert their toxic effects through damage to the respiratory tract. Mechanisms of injury vary with the different agents. The lipid-soluble acrolein penetrates cell membranes and denatures proteins and nucleic acids. Ammonia, hydrogen chloride, and sulfur dioxide react with the moisture of respiratory mucosa to yield ammonium hydroxide, hydrochloric acid, and sulfurous acid, respectively. Chlorine and phosgene generate free radicals, mediating oxidative stress on cellular membranes.

Inhalation of soot and aerosols results in enhanced delivery of irritant gases to the respiratory tract. As soot deposits, adsorbed gases are able to react with the moist mucosal surface. Size of the soot particle determines where it is deposited; particles of 1 to 3 microns are able to reach the alveoli. Particles generated from building fires predominately range from 3 to 5 microns and affect the bronchioles.

Direct heat injury from smoke is confined to the upper airway because of its marked ability to dissipate heat. Because steam has 4,000 times the heat-carrying capacity of hot air, steam inhalation may be rapidly fatal as a result of laryngeal and glottic edema, thermal tracheitis, and hemorrhagic edema of the bronchial mucosa.

Smoke inhalation injury is a product of the inherent toxicity of the TCPs, the victim's minute ventilation, and the duration of exposure. Duration of exposure may be prolonged by anxiety; confusion; impaired visibility as a result of darkness, tearing, smoke,

and physical obstacles; respiratory distress and altered cognition from TCP exposure; a low ambient oxygen concentration; and impaired awareness and mobility from drug and alcohol intoxication, physical handicaps, or extremes of age.

Inhaled particles and toxic gases damage mucosal cells and alveoli, triggering release of inflammatory mediators. Chemotaxins actuate diffuse protein-rich exudate formation. Increased vascular permeability results in interstitial edema. There is increased airway resistance, decreased lung compliance, and bronchoconstriction; acute lung injury may ensue 12 to 24 hours after injury with lung injury scores typically reaching their nadir 72 hours following initial insult. Severity of inhalation injury correlates with alveolar neutrophilia, enhanced production of inflammatory mediators, elevated COHgb, prolonged mechanical ventilation and intensive care unit (ICU), and hospital length of stay (3).

Among firefighters, the type of respirator used influences the risk of smoke inhalation. Atmosphere purifying respirators (APRs) protect against some inhaled particles but not heated gases or CO; oxygen-supplying, self-contained breathing apparatus (SCBA) is the only NIOSH-approved respirator for firefighting. If oxygen is supplied via a demand valve requiring negative inspiratory pressure, smoke inhalation may occur if the mask does not fit tightly. With continuous positive-pressure devices, smoke inhalation will not occur unless the oxygen supply, which typically lasts 20 to 30 minutes, runs out. If either type of mask is removed during clean-up activities after the flames are extinguished, smoke inhalation may still occur. Wildfire fighters do not typically wear oxygen masks or APRs and may be at special risk for inhalation injury.

Smoke inhalation injuries pose significant potential for mass casualties. A train hauling hydrochloric acid, hydrofluoric acid, and acetic acid derailed in Baltimore in July 2001, causing a fire that burned for 5 days and sent hundreds of people to local EDs (4). In November 2000, 155 people died, most of them from smoke inhalation, after a fire broke out in a cable car traveling through a tunnel in Austria. In the 1990 Happy Land Social Club fire in New York City, all 87 deaths were due to smoke inhalation (5).

CLINICAL PRESENTATION

Respiratory signs and symptoms are the primary clinical manifestations of smoke inhalation toxicity. Clinical effects range from transient respiratory tract irritation to severe upper airway compromise and respiratory failure. Cough is often the first symptom. Other initial responses include increased mucous secretion and sneezing. Upper airway involvement results in hoarseness and stridor. Injury to the lower respiratory tract results in crackles and/or wheezing. Breath sounds may be inaudible in cases of severe bronchospasm. Important signs of potential inhalation injury include cough, dyspnea, hoarseness, soot in the oral cavity, singed nasal hair, edema of the posterior pharynx, burns to the face, and any major burn to the body.

Smoke inhalation may cause systemic manifestations as well. Examination of the eye may reveal the irritant effects of increased tearing, conjunctival injection, and blepharospasm. Progressive airway compromise and toxicity from agents with systemic effects, notably carbon monoxide, will produce signs and symptoms of hypoxia—tachycardia, tachypnea, dizziness, headache, nausea and vomiting, chest pain, and deteriorating mental status manifesting as agitation, confusion and ultimately seizures, coma, and death.

Laboratory evaluation may detect hypoxemia, metabolic acidosis, and elevated lactate levels, COHgb, and methemoglobin fractions. The electrocardiogram (ECG) may detect dysrhythmias or evidence of myocardial ischemia or infarction.

DIFFERENTIAL DIAGNOSIS

Patients with smoke inhalation are usually easily identified by history but may have concomitant dermal burns, traumatic injuries, or drug or alcohol intoxication and may be victims of arson, attempted murder, or attempted suicide. For patients presenting with coma and shock, hypoglycemia, intracranial hemorrhage and diffuse brain injury, spinal cord injuries, hypovolemia, myocardial injury, carbon monoxide poisoning, cyanide poisoning,

methemoglobinemia, alcohol intoxication, and drug overdose must also be considered.

ED EVALUATION

Significant smoke inhalation injuries may be delayed after exposure. History of entrapment, fire within an enclosed space, and altered consciousness at the scene should raise the suspicion of inhalation injury. Key risk factors associated with inhalation injury are in Table 337.3. The history should address the nature of burning material, presence of steam, evidence of trauma or suicidality and, for rescuers presenting as patients, the type of mask used.

TABLE 337.3
Risk Factors Associated with Inhalation Injury

Initial Exposure	Symptoms	Signs
Entrapment	Cough	Soot in the oral cavity
Fire in an enclosed space	Shortness of breath	Singed nasal hair
Loss of consciousness at the scene	Hoarseness	Pharyngeal edema
Facial or neck burns; any major burn		
		Stridor
		Crackles/wheezing
		Altered mental status

Examination begins with obtaining vital signs and oxygen saturation, however, transcutaneous pulse oximetry overestimates the true oxygen saturation in the presence of COHgb and methemoglobin. Co-oximetry directly measures an accurate oxygen saturation even in the presence of dyshemoglobinemias. A trauma survey with attention to signs associated with increased risk of smoke inhalation including facial burns, singed facial hair, soot in the nasal passages and airway, and burns involving extensive body surface area (>15%) should follow. The eyes in comatose patients or those with eye complaints should be examined with fluorescein staining to detect corneal burns and lacerations. Other causes of

altered mental status including drug and ethanol intoxication should be considered. Repeat examinations should focus on respiratory status and alterations in mental status. Lung injury scores typically worsen, reaching their nadir about 72 hours after the initial smoke inhalation.

COHgb and methemoglobin should be measured by co-oximetry. An elevated COHgb fraction in a fire victim is an indicator of significant exposure to combustion products and is associated with a markedly increased risk of smoke inhalation injury and toxicity. However, a low or undetectable COHgb concentration does not rule out the possibility of developing even severe inhalation injury.

Whole-blood cyanide levels are not timely but a plasma lactate concentration >8 mmol/L refractory to adequate ventilation, oxygenation, and perfusion is a surrogate marker of cyanide toxicity in the setting of smoke inhalation (6). Methemoglobin should be determined in symptomatic patients, particularly with cyanosis that does not improve with supplementary oxygen (Chapters 329 and 335).

Blood gas measurements should be obtained to assess arterial oxygenation, alveolar ventilation, and the presence of metabolic acidosis. Initially, the blood gas of even a significantly injured patient may be normal; serial measurements are recommended.

An ECG and a chest radiograph are recommended in symptomatic patients, especially in those with pre-existing cardiovascular or pulmonary disease. Chest radiographs may appear normal early in the course of smoke inhalation and therefore lack sensitivity as indicators of inhalation injury. Early findings, if present, are subtle: perivascular cuffing, bronchial wall thickening, and subglottic edema (7). Serial chest radiographs, however, may be very useful in monitoring disease progression. Common complications that do not typically manifest radiographically until more than 24 hours after the initial insult include acute lung injury/acute respiratory distress syndrome, aspiration, volume overload, and infection.

Fiberoptic bronchoscopy is considered the gold standard for diagnosis and evaluation of inhalation injury. Chest CT scan at time of hospital admission appears to complement bronchoscopy in

predicting severity of inhalation injury. Bronchial wall thickening measured by CT correlates with subsequent development of pneumonia and other markers of severity including ICU stay and ventilator requirement (8).

KEY TESTING

- Obtain a COHgb level, chest x-ray, and ECG in all patients with signs of smoke inhalation and/or cardiopulmonary symptoms
- Obtain a lactate level to evaluate for potential cyanide toxicity in seriously ill patients
- Obtain a methemoglobin level in patients with cyanosis and/or other signs including tachycardia, tachypnea, and altered mental status
- Consider early bronchoscopy in admitted patients
- Consider testing for ethanol and other drugs for altered mental status

ED MANAGEMENT

Prehospital directives include the rapid, safe removal of victims from the scene by those with adequate training and protection. Basic and advanced life-support measures are instituted as indicated, including cervical spine immobilization with trauma. Supplemental oxygen is indicated for all patients. Whether a patient should be transported to a burn center, trauma center, or hyperbaric facility is determined by local practice guidelines. Intravenous access and cardiac monitoring may be established en route.

On arrival to the ED, upper airway patency must be determined immediately. Airway compromise may be present initially, rapidly ensue, or develop insidiously over the next few hours. Failure to appreciate the potential for rapid decline in airway status is the major pitfall in managing the smoke inhalation patient. The factors that best correlate with the need for intubation and edema of either the true or false vocal cords are soot in the oral cavity, facial burns, and/or body burns (9). Early endotracheal intubation, performed in a controlled setting before edema makes it impossible, may be life-

saving and should be undertaken when these risks are present. In the patient with the edematous or difficult airway, fiberoptic laryngoscopy, flexible intubation guides, intubation laryngeal masks, retrograde intubation, transtracheal jet ventilation, and ultimately cricothyroidotomy may be necessary for establishing tracheal intubation. Aggressive rehydration of the burn victim may also cause airway edema requiring early intubation.

Early consultation for fiberoptic bronchoscopy should be considered if there is suspicion of inhalation injury. It may also assist in clearing debris from the respiratory tract and permits fiberoptically assisted intubation if required.

β_2-Adrenergic agonists may be useful in improving airflow. Corticosteroids are not indicated with smoke inhalation injury as they are associated with increased incidence of bacterial pneumonia and mortality and are not associated with improved pulmonary function (10). Prophylactic antibiotics also have no demonstrated benefit in the treatment of inhalation injury. Fever and leukocytosis that develop 2 days or more after the injury do suggest infection, and empiric antibiotic treatment that covers *Staphylococcus aureus* and gram-negative organisms should be instituted until culture results become available. Progressive respiratory failure and the development of pneumonitis, acute lung injury/adult respiratory distress syndrome, or other complications may require mechanical ventilation, continuous positive airway pressure, positive end-expiratory pressure, and frequent suctioning of pulmonary secretions.

Trauma-related injuries as a result of falls or explosions and burns must be managed concurrently with inhalation injury. Perform a fingerstick glucose or administer dextrose in the patient with altered mental status and coma and consider naloxone for possible opiate intoxication.

Treat suspected carbon monoxide poisoning with 100% oxygen via nonrebreather mask or endotracheal tube until confirmatory COHgb level is obtained. Consider referral for hyperbaric oxygen therapy (see Chapter 327). Suspect cyanide poisoning in patients

with coma and hypotension and treat with an antidote (see Chapter 329). Hydroxocobalamin (Cyanokit) does not induce methemoglobinemia and may be safely administered to the smoke inhalation patient with suspected cyanide toxicity. The other commercially available antidote kit contains sodium nitrite 3% solution and sodium thiosulfate 25% solution. Sodium nitrite is a potent vasodilator and may cause hypotension. It can also induce methemoglobinemia. When oxygen transport is already compromised, as in a patient with concomitant carbon monoxide poisoning, further impairment by the inducement of methemoglobinemia may exacerbate cellular hypoxia. If hydroxocobalamin is unavailable, a reasonable approach in the smoke inhalation patient with suspected cyanide toxicity, particularly the seriously ill patient with a lactate level >8 mmol/L refractory to resuscitation, is to administer 12.5 g of sodium thiosulfate (50 mL of a 25% solution for adults; pediatric dose, 1.65 mL/kg).

Symptomatic methemoglobinemia and/or concentrations >20% to 30% should be treated with methylene blue (see Chapter 335).

CRITICAL INTERVENTIONS

- Perform early endotracheal intubation in patients with oropharyngeal burns or edema, soot in the oral cavity, full-thickness circumferential neck burns, stridor, coma, or hypoxemia or respiratory distress unresponsive to oxygen administration.
- Administer 100% oxygen to patients with significant smoke exposure or respiratory symptoms.

DISPOSITION

Indications for admission for observation and further treatment are listed in Table 337.4. Severity of illness and the presence of concomitant burns or traumatic injuries should guide the decision to admit to an ICU, telemetry unit, or floor bed. Patients with carbon monoxide poisoning may require transfer for HBO therapy (see

Chapter 327), and those with significant surface burns or physical injuries may require transfer to a burn or trauma center. Advanced life-support capability should be available during transfer.

TABLE 337.4
Indications for Admission after Smoke Inhalation

Facial or nasal burns
Persistent respiratory symptoms (including cough and chest tightness)
Crackles or wheezing on auscultation
Altered mental status
History of loss of consciousness
Abnormal ABG, CXR, or ECG
History of chronic cardiopulmonary disease

ABG, arterial blood gas; CXR, chest x-ray; ECG, electrocardiogram.

Patients in good health who are asymptomatic (on arrival or after a short period of oxygen therapy) and have a normal physical examination including pulse oximetry, blood gas analysis (while breathing room air), ECG, chest radiograph, and COHgb level may be discharged. These patients should be observed for at least 3 or 4 hours before discharge, and they should be instructed to return immediately if any respiratory symptoms develop. Scheduled follow-up at 24 hours may be prudent.

Common Pitfalls

- Failure to anticipate deterioration despite an initially normal initial physical examination, laboratory evaluation, and chest radiograph and failure to frequently reevaluate the respiratory status.
- Failure to evaluate and treat for coexisting carbon monoxide poisoning, drug or alcohol intoxication, traumatic injuries, and psychiatric problems.
- Failure to give oxygen to all patients (including those with chronic obstructive pulmonary disease).

- Failure to fluid-resuscitate patients with trauma or surface burns for fear of exacerbating the edema of inhalation injury.
- Failure to recognize the potential hazards of inappropriate corticosteroid and antibiotic administration.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Christopher H. Linden to the content of this chapter.

PART 8 • PSYCHOTHERAPEUTIC AGENTS

CHAPTER 338 Antipsychotic Agents

Landen Rentmeester and Richard F. Clark

Antipsychotic agents encompass a class of pharmaceuticals originally designed to treat the psychotic features of mental illnesses such as schizophrenia, schizoaffective disorder or acute psychosis but have also been found useful to treat nausea, agitation, hiccoughs, and tics. These medications, especially the older typical antipsychotics, have also been called "neuroleptics" or "major tranquilizers." Antipsychotics are generally divided into the "typical" and "atypical" agents. The "typical" agents were the first antipsychotics to be developed, and were effective in treating hallucinations, agitation, delusions, and behavioral disturbances, the "positive" symptoms of schizophrenia. These older medications are also associated with the development of motor disturbances collectively known as the extrapyramidal syndrome (EPS). The newer "atypical" antipsychotic medications were developed to minimize extrapyramidal effects but were also found to be more effective in treating the "negative" symptoms of schizophrenia, such as alogia, avolition, flattened affect, and social withdrawal (1).

Butyrophenones (e.g., haloperidol), dephenylbutylpiperidines (e.g., pimozide), and phenothiazines (e.g., thioridazine) are the three major classes of the typical antipsychotics, whereas the benzamides (e.g., metoclopramide), diazepines (e.g., olanzapine), indoles (e.g., risperidone), and quinolinones (e.g., aripiprazole) are the four major classes of atypical antipsychotics. The antipsychotic action of each of these medications is thought to be due to blockade of excessive dopamine–mediated neurotransmission in the central nervous system (CNS) (2). Antipsychotic medications also have pharmacologic

effects outside of the dopaminergic pathways, blocking alpha-adrenergic (α_1), histaminergic (H_1), muscarinic (M_1), and serotonergic (5-HT_{2A}) receptors (3).

The atypical agents have lower and more selective (mesolimbic) D_2 potency and higher M_1 and/or 5-HT_{2A} antagonist activity than the typical agents (3). Although higher doses are required for antipsychotic effect, they are less likely to cause acute dystonia and tardive dyskinesia and have minimal or no effect on prolactin secretion. Only clozapine, olanzapine, and quetiapine have significant antimuscarinic activity. Atypical antipsychotics cause EPS less frequently than the older agents; whereas lurasidone may be more likely to promote extrapyramidal symptoms than other atypical agents (4). For unclear reasons, all atypical antipsychotics can cause hyperglycemia and an FDA black box warning recommends that diabetics and those at risk for diabetes (e.g., obese patients and those with a family history of diabetes) be monitored for this complication at the start of therapy. Atypical antipsychotics, especially olanzapine and clozapine, seem to put patients at risk for "metabolic syndrome," a constellation of weight gain, insulin resistance, glucose intolerance, and hyperlipidemia (3). Among the first-generation antipsychotics agents, chlorpromazine is most frequently associated with weight gain (4).

Most antipsychotics are much more potent H_1 blockers than diphenhydramine. Antimuscarinic (M_1) potency correlates directly with sedation and inversely with the incidence of EPS. Chlorpromazine, chlorprothixene, and thioridazine have potent sedative effects, whereas haloperidol, zotepine, and chlorpromazine are commonly associated with EPS (4).

Hypotension and miosis are often seen with both therapeutic dosing and overdose of both typical and atypical antipsychotics, a result of peripheral α-adrenergic blockade. Hypotensive effects are primarily orthostatic and systolic in nature. Concomitant therapy with either β-receptor agonists (e.g., epinephrine) or β-receptor blockers (e.g., propranolol) may result in severe hypotension. All the antipsychotics, particularly chlorpromazine, clozapine, and loxapine

lower the seizure threshold and can induce epileptiform encephalogram (EEG) discharge patterns at therapeutic dosages and in overdose, probably because of inhibition of γ-aminobutyric acid (GABA) receptors, norepinephrine reuptake, or antimuscarinic effects.

Antipsychotics also have dose-related effects on cellular membrane ion channels (3). Phenothiazines (particularly chlorpromazine, thioridazine and its metabolite mesoridazine) block sodium channels, which in overdose may cause local anesthetic or quinidine-like (class Ia) effects and result in dysrhythmias, myocardial depression, and delayed depolarization with conduction disturbances, especially QRS prolongation. QRS prolongation is most often seen with quetiapine but is rarely an isolated finding with atypical agents (3). Droperidol, haloperidol, sertindole (Serlect), thioridazine, most atypical antipsychotics, and most other antipsychotics also block potassium channels, resulting in delayed repolarization with QT interval prolongation. Higher IV doses of the atypical agents such as ziprasidone may also cause this effect. Electrocardiogram (ECG) changes such as prolonged PR and QT intervals, ST-segment depression, T-wave abnormalities (biphasic, blunting, inversion, notching, widening), and increased U waves occur with both therapeutic and excessive doses (3,6). Reports of QT prolongation leading to torsades de pointes (polymorphic ventricular tachycardia), ventricular tachycardia (VT), and death prompted a controversial box warning for IV droperidol in 2001 and IV haloperidol in 2007 that an ECG be obtained prior to its use, that it not be given to those with QT prolongation ($>$440 ms in males and 450 ms in females), and for cardiac monitoring for 2 to 3 hours after its use (7). Ventricular dysrhythmias, asphyxia from aspiration, or respiratory depression from seizures have been postulated as the cause of sudden death with therapeutic doses of antipsychotics, particularly phenothiazines (6).

Gastrointestinal (GI) absorption of antipsychotics is relatively slow and unpredictable, with peak levels occurring 2 to 4 hours after ingestion. Bioavailability after parenteral administration is two to ten times greater than with oral dosing because presystemic (GI and

hepatic) metabolism occurs after ingestion. Antipsychotics are highly bound to plasma proteins, are highly lipophilic, and have large volumes of distribution (10 to 40 L/kg). Thus, therapeutic serum concentrations are low (one to several hundred ng/mL), and drug accumulates in the brain and fat and readily crosses the placenta.

Therapeutic doses vary widely (see Table 338.1) and are adjusted on the basis of clinical response and side effects, not by monitoring drug levels. Pharmacologic effects generally last 24 hours or more, allowing once or twice daily dosing. Elimination occurs slowly by hepatic metabolism, with serum concentration half-lives averaging 20 to 40 hours. Hepatic metabolism yields multiple metabolites, some of which are pharmacologically active (aripiprazole, risperidone, quetiapine, thioridazine and clozapine are known to have active metabolites). Metabolites are eliminated by urinary and, to some extent, biliary excretion and can be detected in the urine for more than a month after the cessation of chronic therapy. Concomitant use of agents that inhibit or stimulate hepatic cytochrome oxidases (CYP isoenzymes) can increase or decrease, respectively, the blood level and effect of these agents.

TABLE 338.1
Antipsychotic Agents

Structural Class	Generic Name	Trade Name	Oral Dose (Adult, mg)
Traditional (Typical) Antipsychotics			
Benzamide	Trimethobenzamide	Tigan	250–300
Butyrophenone	Droperidol	Inapsine	2.5–10.0[c]
	Haloperidol	Haldol	0.5–2.0
Dibenzoxazepine	Loxapine	Loxitane	10–50
Diphenylbutylpiperidine	Pimozide	Orap	0.5–1
Indole	Molindone	Moban	5–25
Phenothiazine	Chlorpromazine	Thorazine	25–50
	Fluphenazine	Prolixin	2.5–10
	Mesoridazine	Serentil	25–100
	Perphenazine	Trilafon	4–16
	Prochlorperazine	Compazine	5–10
	Promazine	Sparine	25–100
	Promethazine[a]	Phenergan	25–50
	Thiethylperazine[a]	Torecan	10–30
	Thioridazine	Mellaril	25–100
	Trifluoperazine	Stelazine	2–5
	Triflupromazine	Vesprin	5–15[c]
	Trimeprazine[b]	Temaril	2.5
Thioxanthene	Chlorprothixene	Taractan	25–50
	Thiothixene	Navane	2–15
Atypical Antipsychotics			
Benzisoxazole	Risperidone	Risperdal	1–3
Dibenzodiazepine	Clozapine	Clozaril	200–600
Dibenzothiazepine	Quetiapine	Seroquel	50–250
Piperazine	Ziprasidone	Geodon	20–80
Quinolone	Aripiprazole	Abilify	5–30
Thienobenzodiazepine	Olanzapine	Zyprexa	10–15

[a]Used only as antiemetic.
[b]Used only as antipruritic.
[c]Parenteral dose.

Side effects of therapeutically dosed antipsychotics include antimuscarinic sequelae (see Chapter 344, “Anticholinergic Agents”), extrapyramidal symptoms (EPS), neuroleptic malignant syndrome (NMS), hypotension, and sedation (3,4). Clozapine can cause agranulocytosis, myocarditis, and cardiomyopathy (3).

Antipsychotic agents have a high therapeutic index. Of the thousands of overdoses reported to poison centers each year, only 4% to 6% of patients develop serious toxicity, and <1% die. Thioridazine (because of its tricyclic antidepressant-like

cardiotoxicity) or mixed overdoses are involved in most successful suicides (3,5). Toxic doses for most of these agents are not well established and vary greatly.

CLINICAL PRESENTATION

Mild poisoning includes ataxia, confusion, lethargy, and slurred speech. Hypotension, both orthostatic and diastolic, may be caused by α-adrenergic blockade. Tachycardia may develop from antimuscarinic effects or as a reflex tachycardia. Miosis due to α blockade is common, but mydriasis due to antimuscarinic effects can also occur. Antimuscarinic signs and symptoms (Chapter 344, "Anticholinergic Agents") are often present, and patients may be hyperreflexic. Prolonged PR and QT intervals and nonspecific ST-segment, T-wave, and U-wave abnormalities may be seen.

Moderate poisoning is characterized by sedation, with or without respiratory depression, and systolic hypotension accompanied by reflex tachycardia. Hyperthermia and hypothermia (less common) may be present. Paradoxical agitation, delirium, and tachypnea are reported but are likely antimuscarinic effects. Sialorrhea may be seen after clozapine overdose and at therapeutic doses.

In severe poisoning, deep coma with loss of brainstem and deep tendon reflexes, apnea, hypotension, tachycardia, and cardiac dysrhythmias (especially with thioridazine and mesoridazine) are seen. Tachydysrhythmias, rare bradydysrhythmias, and cardiac conduction delays (especially with thioridazine and mesoridazine) may occur. QT interval prolongation and torsades de pointes are reported after haloperidol, loxapine, phenothiazine, pimozide quetiapine, risperidone, sertindole, and ziprasidone overdose and during high-dose IV droperidol and haloperidol therapy (6). Seizures are rare, except with chlorpromazine, loxapine, and clozapine (3).

The onset of symptoms of poisoning occurs within 1 to 2 hours of acute ingestion, with maximal severity usually apparent in 2 to 6 hours. Children appear more susceptible to toxicity than adults. Recovery can be expected within several hours to several days, depending on the severity and drug ingested. The mortality rate from acute poisoning is $<1\%$.

EPS may occur early (within days), or late (after 3 months or more) after beginning antipsychotic therapy, increasing the dose, or changing the agent. Dyskinesia or acute dystonic reactions (see Chapter 340), akathisia, NMS, and parkinsonism occur early whereas tardive dyskinesia or dystonias occur late. These idiosyncratic reactions are most common with older high-potency agents. Akathisia, a subjective sensation of motor restlessness, occurs in about 20% of patients treated with traditional antipsychotics and is sometimes associated with severe parkinsonism (see Chapter 162, "Parkinsonism and Other Movement Disorders"). Transient akathisia has been observed in up to 50% of those treated with IV droperidol or prochlorperazine for headache, nausea, and vomiting. Women are affected more often than men. Patients complain of feeling restless, jittery, and tense; they cannot sit or stand still and when standing may shift their weight from foot to foot as if walking in place. Vital signs remain normal. Semipurposeful or purposeless limb movements (especially of the lower extremities), frequent shifting of body position, and tremors and myoclonic jerking may be noted. Focal perioral tremor, also known as *rabbit syndrome,* is a rhythmic motion of the mouth and lips, resembling the chewing movements of a rabbit. In contrast to oral tardive dyskinesia, tongue movements do not occur in rabbit syndrome.

NMS can be precipitated by concurrent illness, surgery, dehydration, heat stress, acute agitation and, very rarely, by acute overdose of antipsychotic agents. It is estimated to occur in $<1\%$ of patients treated with antipsychotics for psychiatric conditions and appears to be more common with parental therapy. Of the cases linked to atypical antipsychotics, clozapine has been implicated in many of them, despite the relative rarity of extrapyramidal symptoms with this drug (3). NMS is characterized by elevated body temperature ($>38^{\circ}C$ or $100.4^{\circ}F$), altered mental status ranging from confusion and delirium to coma, autonomic dysfunction, increased motor activity, and laboratory abnormalities. Autonomic disturbances include hypertension ($>150/100$ mm Hg; diastolic or systolic blood pressure increased 20 or 30 mm Hg above baseline, respectively), tachycardia (heart rate >90 to 100 or increased by 30

beats/min), increased respiratory rate (alternatively dyspnea, hypoxemia, or respiratory failure), diaphoresis (often profuse), sialorrhea, and incontinence. Hypotension, rather than hypertension, sometimes occurs. Although "lead pipe" rigidity is the classic motor finding, lesser increases in muscle tone, akinesia, dystonia, dyskinesia, tremor, choreiform movements, opisthotonus, and parkinsonism (cogwheel rigidity) may be present. Hyperactivity of pharyngeal muscles may result in dysarthria, dysphagia, dysphonia, and trismus. Laboratory abnormalities include leukocytosis (white blood cells $>14{,}000/mm^3$ without a left shift), rhabdomyolysis (creatine phosphokinase >500 IU/mL or three times normal), and markedly elevated white blood cell count. Hyponatremia, hypernatremia, or hypokalemia may be present. Onset is typically insidious, and resolution occurs slowly, sometimes taking up to 2 weeks. Complications include aspiration pneumonia, coagulopathy, renal failure, rhabdomyolysis, myocardial infarction, heart failure, dysrhythmias, and venous thromboembolism. The mortality rate of NMS ranges from 12% to 20% and is primarily related to complications. Sequelae include dysarthria, dysphagia, myoclonus, and weakness.

DIFFERENTIAL DIAGNOSIS

Antidysrhythmic, tricyclic antidepressant, antimuscarinic, anticonvulsant, opioid, and sedative–hypnotic toxicity may all cause CNS or CV effects similar to those seen in antipsychotic poisoning. CNS infection, infarction, and trauma should also be considered in the differential diagnosis of antipsychotic poisoning.

EPS from antipsychotics may be misdiagnosed as anxiety or agitation related to an underlying psychiatric disorder. EPS can occur when beginning or increasing therapy with neuroleptic or nonneuroleptic dopamine antagonists (e.g., hydroxyzine, metoclopramide, reserpine), discontinuing or decreasing therapy with a dopamine agonist (e.g., amantadine, bromocriptine, carbidopa, levodopa, lithium, pergolide, pramipexole, ropinirole) or use of a catecholamine degradation inhibitor (e.g., catechol-o-methyltransferase inhibitors such as entacapone and tolcapone). The

differential diagnosis of NMS also includes dystonic reactions, lithium, monoamine oxidase inhibitor, salicylate, stimulant, and strychnine poisoning, heat stroke, malignant catatonia, malignant hyperthermia (MH), encephalitis, meningitis, pheochromocytoma, serotonin syndrome (SS), tetanus, thyrotoxicosis, and withdrawal states.

Distinguishing NMS from MH or SS (see Chapter 343, "Serotonin Reuptake Inhibitors") is difficult as clinical features overlap. The correct diagnosis relies primarily on the drug exposure history. Onset after general anesthesia or ketamine administration strongly suggests MH. Use of proserotonin drugs is suggestive of SS. SS also begins more abruptly and resolves more quickly than NMS (over hours rather than days). Myoclonus, hyperreflexia, and shivering are rare in NMS but common in SS.

Although specific criteria have been proposed for the diagnosis of NMS, the required elements are not universally agreed on, and patients can have NMS without manifesting a classic or characteristic feature (e.g., fever or rigidity). Diagnosing patients with attenuated forms of NMS relies primarily on the clinical settings and history of drug exposure (3).

ED EVALUATION

A complete history should always be obtained from the patient and, when possible, corroborated with the person who found or brought the patient to the emergency department (ED). The name, quantity, and time of ingestion should be determined. In patients taking antipsychotics for therapeutic purposes, a history of a recent medication or dosage change, illness, or surgery is important.

The physical examination should focus on the vital signs, CV system, and neurologic function. An initial rhythm strip and subsequent 12-lead ECG should be evaluated for prolonged QRS or QTc intervals or other dysrhythmias. Pulse oximetry can monitor oxygenation and end tidal carbon dioxide monitoring can monitor adequacy of ventilation. Because phenothiazines can be radiopaque, abdominal radiographs may be useful to quantify or verify ingestion, however, the lack of x-ray visualization does not rule out ingestion

or imply successful gastric decontamination. Laboratory evaluation should include a complete blood count, electrolytes, blood urea nitrogen, creatinine, and glucose to rule out concomitant abnormalities, urinalysis to check for myoglobin, and serum creatine kinase (CK) to evaluate for rhabdomyolysis. In patients with hyperthermia, liver function tests and coagulation profiles are useful to determine hepatic injury or disseminated intravascular coagulation. Computed tomography (CT) of the head and lumbar puncture should be considered as intracranial hemorrhage and meningitis may present in a similar manner as NMS. In seriously ill patients, toxicologic analysis of the urine and serum may confirm the identity of the agent, but results will often not be readily available. Quantitative drug levels are not helpful in predicting clinical toxicity or in guiding treatment. Urine drug immunoassays most often do not detect antipsychotics and are of little value in treating a patient who presents with an acute medication overdose. Although neither sensitive nor specific, the Forest, Mason, and Phenistix colorimetric urine tests may be positive with phenothiazine ingestions and can be used to rapidly screen for these agents.

KEY TESTING

- 12-lead ECG to evaluate for QRS or QTc interval abnormalities.
- Complete blood count, basic metabolic profile including magnesium, calcium, and phosphorus levels.
- Consider liver transaminase, creatine kinase, and coagulation panel.
- Head CT and lumbar puncture if altered mental status is of unclear etiology.
- Consider physostigmine challenge in the appropriate clinical setting.

ED MANAGEMENT

Advanced life-support measures should be instituted as necessary. All patients require cardiac and respiratory monitoring along with IV access. Core temperature should be monitored for evidence of hypo-

or hyperthermia with appropriate cooling or heating measures. Endotracheal intubation may be required for respiratory failure, CNS depression, or when paralysis is indicated for significant hyperthermia. If paralysis is required, nondepolarizing paralytic agents such as rocuronium (0.6 to 1 mg/kg IV) or vecuronium (0.08 to 0.1 mg/kg IV) are recommended, because succinylcholine (and other depolarizing neuromuscular blockers) can cause MH and potentiate rhabdomyolysis and hyperkalemia in antipsychotic-poisoned patients.

Hypotension should initially be treated with IV crystalloids. Norepinephrine and/or phenylephrine are the drugs of choice for refractory hypotension due to their α_1-adrenergic properties. Dopamine may be ineffective or even exacerbate the hypotension associated with antipsychotics agents. At modest doses, dopamine's activity may be impaired because it is unable to enter presynaptic terminals through the blocked catecholamine reuptake pump caused by the antipsychotic, whereas at higher doses, dopamine may encounter α-blocking effects of these drugs, leading potentially to unopposed β-receptor stimulation of blood vessels and vasodilation.

Unstable tachydysrhythmias should be treated with electrical cardioversion or defibrillation for ventricular fibrillation and nonperfusing monomorphic or polymorphic VT. If the QRS complex is wide prior to or after termination of unstable tachydysrhythmias, sodium bicarbonate (1 mEq/kg IV) may be effective (see Chapter 321, "Antidysrhythmic Drugs and Local Anesthetics," and Chapter 339, "Cyclic Antidepressants"). Amiodarone or lidocaine can also be used to treat refractory stable VT. Type Ia (disopyramide, quinidine, procainamide), Ic (encainide, flecainide, propafenone), II (β blockers), and IV (calcium channel blockers) antidysrhythmic drugs should be avoided in wide complex tachydysrhythmias. If the QTc interval is significantly prolonged (typically greater than 500 ms) or torsades de pointes is observed, magnesium (50 to 100 mg/kg IV over 1 hour), isoproterenol, or overdrive pacing are preferred. Increasing the heart rate shortens the QT interval and is recommended for preventing the recurrence of torsades de pointes. Bradydysrhythmias should be treated according to Advanced Cardiac

Life-Support protocols. Complete heart block may require temporary cardiac pacing after underlying metabolic abnormalities are corrected.

Seizures should be treated with benzodiazepines (e.g., lorazepam, 0.05 mg/kg IV, or diazepam, 0.1 mg/kg IV). Barbiturates (e.g., phenobarbital, 18 to 20 mg/kg IV, or pentobarbital, 5 mg/kg IV) and propofol may be added if necessary. Patients with refractory seizures may require propofol infusion or neuromuscular paralysis to prevent complications such as hyperthermia and rhabdomyolysis. Continuous or serial EEG monitoring should be instituted during paralysis. Aggressive IV fluid resuscitation with or without alkalinization of the urine may prevent myoglobinuric renal failure in patients with rhabdomyolysis. Physostigmine can reverse the delirium resulting from muscarinic receptor blockade if the QRS length on ECG is normal and if there is no seizure activity (see Chapter 344, "Anticholinergic Agents"). This is typically dosed in adults as 1 to 2 mg infused over 5 minutes. The patient should respond within 10 minutes, but the effect will be transient, lasting 45 minutes to an hour and the dose can be repeated. Antimuscarinic reversal is classified as a return to normal mental state which provides a window of opportunity to obtain confirmation of the patient's overdose and avoid the need for a more extensive diagnostic workup (8).

Early and aggressive treatment of muscular hyperactivity and hyperthermia in patients with NMS appears to improve outcome. Initial management includes benzodiazepines, but therapeutic paralysis may be required for patients with refractory seizures or severe hyperthermia. Active cooling measures (e.g., cooling blankets, ice packs, and evaporative cooling methods) are necessary for most severely hyperthermic patients. Antipyretics are not effective. The antipsychotic therapy must be discontinued. Although dantrolene (2.5 to 10 mg/kg/d IV) has been proposed to treat NMS, there are no convincing clinical data or theoretical reasons to suggest that it would be efficacious. The release of calcium from muscle sarcoplasmic reticulum is reduced by dantrolene through inhibition of ryanodine receptors. This mechanism is involved in the

pathogenesis of MH, but does not seem to cause or contribute to NMS. However, if MH cannot be definitely excluded, dantrolene sodium can be attempted as this may be a lifesaving intervention.

Activated charcoal may be considered in patients with a secure airway and ingestion within 1 hour who do not have suspected caustic injury or are at risk for aspiration. Repeated oral doses of activated charcoal are not beneficial for these poisonings. Diuresis, dialysis, and hemoperfusion are not effective. Patients in cardiovascular collapse from severe antipsychotic overdose have responded to use of lipid emulsion therapy (Intralipid) and extracorporeal life-support and these may be considered if resources are available (9,10)

Patients with EPS who require continued antipsychotic therapy can be managed by reducing the dose, switching to an agent of lower potency, or giving an antimuscarinic agent (e.g., benztropine or diphenhydramine). Benzodiazepines, clonidine, propranolol, and short-acting barbiturates have also been used with moderate success. Patients who develop akathisia after a single therapeutic dose of antipsychotic (e.g., for migraine or vomiting) should be reassured that symptoms will resolve within 24 hours.

CRITICAL INTERVENTIONS

- Establish IV access, cardiac monitoring, and ECG for QRS and QT intervals, and frequently reevaluate the vital signs and clinical status.
- Obtain a core temperature and CK in patients with suspected NMS (altered mental status, autonomic dysfunction, and muscle hyperactivity).
- Treat muscle hyperactivity, and seizures aggressively with benzodiazepines, barbiturates, therapeutic paralysis for refractory cases.
- Use physical cooling measures for hyperthermia, and alkaline diuresis for rhabdomyolysis.
- Administer sodium bicarbonate to patients with monomorphic VT. Lidocaine or amiodarone may be used in refractory VT.

- Administer magnesium, isoproterenol, or overdrive pacing to patients with torsades de pointes.

DISPOSITION

Asymptomatic patients with an acute overdose should be observed for 6 hours. Symptomatic patients with significant CNS depression, hypotension, seizures, or dysrhythmias should be admitted to an intensive care unit (ICU) or a monitored observation area. Alert patients with a history of overdose and abnormal ECG should be monitored as ECG abnormalities can be seen with therapeutic doses and have been implicated as a cause of sudden death.

Except for NMS, EPSs are not life-threatening and do not require admission, although the symptoms may be quite stressful to patients. Medication adjustment may be appropriate, but this should be done in consultation with the patient's psychiatrist. Patients with NMS will require ICU admission. Patients requiring transfer to a facility capable of providing intensive care should be accompanied by advanced life-support personnel and should have cardiac monitoring en route.

Common Pitfalls

- Failure to appreciate that antipsychotics can prolong QRS and QTc intervals, causing cardiac dysrhythmias.
- Failure to appreciate that atypical antipsychotics, although less likely to cause EPS than traditional agents, are more sedating and cause similar CV toxicity.
- Failure to appreciate that antipsychotics can lower seizure threshold.
- Failure to appreciate that attenuated forms of NMS can occur and to discontinue antipsychotic therapy in patients with any manifestation of NMS.
- Administration of Type Ia, Ic, II (β blockers), and IV (calcium channel blockers) antidysrhythmic agents in wide complex tachydysrhythmias.

- Failure to appreciate that dopamine is not as effective as norepinephrine or phenylephrine in treating antipsychotic-induced hypotension.

CHAPTER 339 Cyclic Antidepressants

Jon B. Cole

Cyclic antidepressants (CAs) have been used to treat depression since the 1950s. Additional therapeutic use has included attention deficit disorder, anorexia nervosa, obsessive-compulsive disorder, phobias, chronic pain, migraine headaches, enuresis, and peptic ulcer disease. The term *CAs* refers to a family of drugs that have similar structure, pharmacology and toxicity (Table 339.1). In the 1980s, another group of antidepressants, the selective serotonin reuptake inhibitors (SSRIs; see Chapter 343), emerged and their use has superceded that of the CAs. SSRIs offer a wider margin of safety, with less central nervous system (CNS) and cardiovascular (CV) toxicity, compared with the CAs (1). During the 1990s and 2000s, the atypical antipsychotic agents (see Chapter 338) grew in popularity and are also being used to treat depression, especially in association with psychotic disorders. During this time the serotonin and norepinephrine reuptake inhibitors (SNRIs), venlafaxine and duloxetine, as well as the unique norepinephrine and dopamine reuptake inhibitor bupropion also came to prominence. The toxicity profiles of the atypical antipsychotics, SNRIs, and bupropion are dependent on the unique pharmacologic actions of each drug, but several of them share aspects that resemble CA poisoning, including coma, tachycardia, delirium, QTc prolongation, QRS prolongation, shock, and cardiac dysrhythmias. Even with these alternative drug classes, CAs are still commonly used. In 2011, 73 fatalities related to the ingestion of CAs were reported to American poison centers (2). Moreover, overdoses with CA continue to cause more toxicity than overdoses with other antidepressants (3). CAs also are still

commonly prescribed in children, and CA poisoning can be potentially lethal in younger children as well (4).

TABLE 339.1
Antidepressant Agents

Class	Drug	Trade Name(s)
Tricyclics		
Tertiary amines		
	Amitriptyline	Amitid, Amitril, Elavil, Endep, Etrafon, Triavil
	Clomipramine	Anafranil
	Doxepin	Adapin, Sinequan
	Imipramine	Janimine, Presamine, SK-Pramine, Tofranil
	Trimipramine	Surmontil
Secondary amines		
	Desipramine	Norpramin, Pertofrane
	Nortriptyline	Aventyl, Pamelor
	Protriptyline	Vivactil
Tetracyclics		
	Maprotiline	Ludiomil
	Mianserin	Bolvidon, Norval
Dibenzoxazepine		
	Amoxapine	Ascendin
Selective Serotonin Reuptake Inhibitors		
	Fluoxetine	Prozac
	Sertraline	Zoloft
	Paroxetine	Paxil
	Fluvoxamine	Luvox, Faverin
	Citalopram	Celexa, Cipramil, Seropram
	Escitalopram	Lexapro, Cipralex

The pharmacologic properties of the CAs contribute to their toxicity in overdose. In general CAs are highly lipophilic, with large volumes of distribution (Vd = 10 to 50 L/kg), and are highly protein-bound (>95%). The onset of CA toxicity is typically rapid; CAs are rapidly absorbed and quickly distributed to their target

organs. Most CAs are tertiary or secondary amines. Tertiary amines (e.g., amitriptyline and imipramine) are metabolized to their respective secondary amines (e.g., nortriptyline and desipramine), which are also active drugs. Tertiary amines block norepinephrine and serotonin reuptake, whereas secondary amines primarily block norepinephrine reuptake. Amoxapine and maprotiline are CAs that have unique structures that also primarily block norepinephrine reuptake. Tertiary amines have more anticholinergic and antihistaminic effects than the secondary amines. CAs have half-lives of >24 hours. Early reports described delayed recovery from toxicity but improved supportive care, particularly alkalinization therapy, is probably responsible for improving outcomes today. With good supportive care, most CA-poisoned patients make a full recovery within 1 to 3 days.

Therapeutic doses of CAs are typically <5 mg/kg but tolerance does develop with chronic use. Toxicity is often seen with ingestion >10 mg/kg, which is also considered to be a minimum fatal dose. Doses >15 mg/kg often result in severe and potentially fatal ingestions.

The CNS and CV toxicity of CAs result from their pharmacologic actions which include (1) delayed cardiac conduction from sodium-channel blockade, (2) initial sympathomimetic, and late sympatholytic actions resulting from the blockade of norepinephrine reuptake, and (3) anticholinergic, (4) antihistaminic, (5) $GABA_A$ receptor channel, (6) α_1-adrenergic blocking, and (7) block cardiac potassium delayed-rectifier channels. Some CAs present with either predominantly CNS or cardiac toxicity. For example, amoxapine produces seizures, including status epilepticus, but rarely causes cardiac conduction disturbances. In general, newer and safer antidepressants, such as the SSRIs, have a relative absence of sodium-channel blockade, catecholamine reuptake blockade, and anticholinergic effects.

CLINICAL PRESENTATION

CA poisoning may progress rapidly from asymptomatic to cardiopulmonary arrest within minutes as an alert patient may have seizures, become comatose, or develop hemodynamic and cardiac instability. CA-induced seizures typically occur early and are unlikely to recur beyond 12 hours after ingestion but may deteriorate into status epilepticus. Status myoclonic activity is seen with severe poisoning. Vital signs can be unpredictable in CA poisoning. Patients are often initially tachycardic and mildly hypertensive (as a result of the blockade of norepinephrine reuptake and anticholinergic effects), or they may be hypotensive (from α_1 blockade). Later, the metabolism of norepinephrine by enzymes such as catechol-O-methyltransferase (COMT) may lead to a catecholamine depletion state resulting in hypotension, bradycardia, and finally cardiogenic shock. Most patients recover in 24 to 72 hours with good supportive care but refractory hypotension is seen in most fatalities.

Cardiac dysrhythmias include both supraventricular tachydysrhythmias and ventricular dysrhythmias. A wide QRS seen with intraventricular conduction delay from sodium-channel blockade makes it difficult to distinguish ventricular tachycardia (VT) from a supraventricular tachycardia with aberrant conduction. Polymorphous VT (torsades de pointes) has also been reported though this is rare. Aspiration pneumonia is relatively common in comatose patients, and acute respiratory distress syndrome may occur. Rhabdomyolysis and compartment syndrome are additional complications particularly if patients experience status epilepticus or are comatose for a long period of time without medical care.

Patients with ingestions of <15 mg/kg often have a predominant anticholinergic syndrome with minimal cardiac conduction effects. Anticholinergic effects can also occur during recovery from severe poisoning and may last for days. Typical signs and symptoms include tachycardia, hypertension, absent bowel sounds, ileus, and urinary retention. Other anticholinergic effects, such as dilated pupils, flushed hot skin, and dry mucous membranes, however, are more variable. For example, the patient’s pupils may be large if

anticholinergic effects predominate, however if α_1 blockade is prominent, small pupils would be seen. Central anticholinergic findings may vary from agitation to psychosis to coma. Additional neurologic manifestations include choreoathetosis, ataxia, myoclonus, status epilepticus, and coma.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of coma, seizures, and cardiac dysrhythmias includes hypoxia, metabolic abnormalities, serotonin syndrome, and intrinsic neurologic and cardiac diseases. Other drugs with toxicities that can appear similar to CAs include the antidysrhythmics, antihistamines, antimalarials, atypical antipsychotics, dihydropyridine-type calcium-channel blockers, carbamazepine, phenothiazines, tramadol, and propoxyphene. Anticholinergic agents, camphor, cocaine, chloral hydrate, isoniazid, lithium, sympathomimetic poisoning, and drug withdrawal should also be considered.

ED EVALUATION

The history should be obtained from the patient, family, friends, roommates, and available prehospital personnel. The patient's pharmacy records may be useful as well. If possible, the time, amount, and identity of all agents ingested should be determined. When known, the amount of CA ingested can help predict the potential for deterioration. The therapeutic dose of 5 mg/kg should be tolerated by all, including children. Observation without intervention would be the best approach for these patients. Conversely, patients who ingest 15 mg/kg (roughly 1 g for a 70-kg adult) have the potential for serious poisoning.

The physical examination should focus on the vital signs, CV, and neurologic function. Vigilant observation of mental status is required. The potential for seizures and rapid deterioration requires that IV access and continuous cardiac and oxygenation monitoring be initiated immediately. Vital signs and neurologic status should be evaluated continuously, and a limb lead QRS duration (discussion

follows) should be checked every 30 minutes or if the monitor looks suspicious.

An electrocardiogram (ECG) should be performed early in the evaluation. A QRS duration >100 ms is associated with seizures, and a QRS duration >160 ms is associated with ventricular dysrhythmias. Patients with a QRS duration >120 ms who have a seizure are at great risk for sudden CV toxicity including CV collapse (5). More subtle, early ECG changes include a rightward axis of the terminal 40 ms of the QRS in the frontal plane. This manifestation can be quickly assessed by looking for the presence of a wide S wave in leads 1 and aVL, and an R wave in lead aVR (Fig. 339.1). These terminal 40-ms changes are good indicators for sodium-channel blockade, from CA poisoning, but they do not absolutely confirm or exclude the diagnosis.

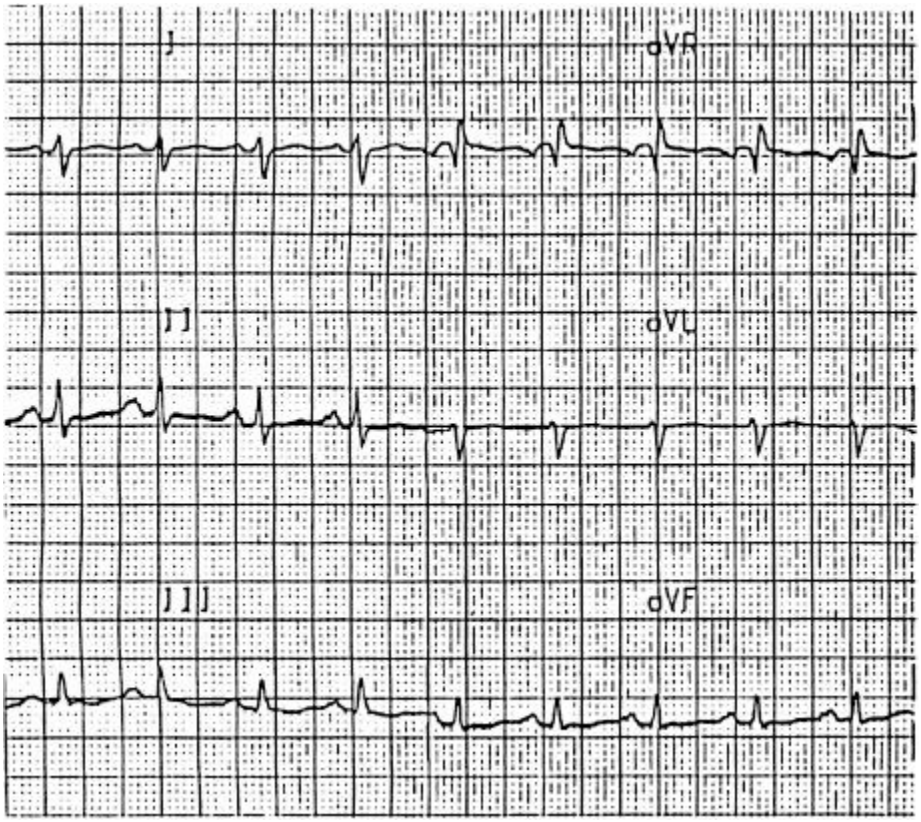

FIGURE 339.1 Terminal QRS changes in CA poisoning.

Other than a lactic acidosis secondary to seizures or shock, CAs are not known to produce biochemical disturbances. However, evaluation of patients with altered mental status or cardiotoxicity includes assessment of serum electrolytes, blood urea nitrogen, creatinine, and glucose. A blood gas, creatine phosphokinase, calcium, magnesium, phosphorus, liver chemistries, and a chest radiograph should be considered for ill patients with abnormal vital signs, significant CNS depression, seizures, or an abnormal ECG. Patients with an intentional ingestion should have a serum acetaminophen concentration to rule-out coingestion.

Drug screening for CAs has no place in the management of the acutely CA-poisoned patient. Urine qualitative immunoassays are the most common form of drug screening for CAs but many other drugs including diphenhydramine, cyclobenzaprine, quetiapine, cyproheptadine, carbamazepine, and most phenothiazines cause false positives. Although serum CA concentrations >1,000 ng/mL generally correlate with significant toxicity, levels do not assist in emergency management. Monitoring the changes on the ECG and the patient's mental status are more clinically useful indicators of ongoing CA toxicity.

KEY TESTING

- ECG and monitoring QRS width and dysrhythmias
- Acetaminophen level to detect coingestion
- Unstable patients need other laboratories for supportive care management
- Urine drug testing and serum levels are not clinically helpful

ED MANAGEMENT

Patients with coma, seizures, hypotension, and dysrhythmias include endotracheal intubation, administration of anticonvulsants, intravenous crystalloids, and serum alkalinization with parenteral sodium bicarbonate boluses.

Parenteral benzodiazepines such as diazepam (5 to 10 mg) or lorazepam (1 to 2 mg) are the agents of choice for the treatment of

seizures. They should be administered to any patient with seizures. Repeat doses may be required. When intubation is required, parenteral benzodiazepines such as lorazepam and diazepam may be useful as well for sedative and anticonvulsant effects, though propofol is a reasonable option if hypotension is not present. If repeat doses of benzodiazepines do not completely control seizures, phenobarbital or propofol should be added. Phenobarbital or propofol may be necessary for the treatment of myoclonus. In the intubated patient, a phenobarbital loading dose of 18 mg/kg is usually sufficient. The dose for propofol sedation of the intubated patient begins with a bolus infusion of 0.5 mg/kg; this can be repeated if blood pressure allows. The dose is titrated to the desired sedation level in increments of 20 to 80 μg/kg/hr as a constant infusion, titrated to the appropriate sedation level. Propofol's rapid onset and offset make it ideal for the management of these ventilated CA-poisoned patients. Seizures should be anticipated so benzodiazepines should be kept at the bedside to minimize the rapidly produced lactic acidosis that may further compromise the cardiac and hemodynamic status. In addition, an intravenous bolus of 1 to 2 ampules (44 to 100 mEq) of hypertonic sodium bicarbonate is recommended as adjunctive treatment for seizures.

Hypotension should be treated with intravenous crystalloid boluses. This treatment should overcome hypotension from α-adrenergic blockade and mild dehydration. For more seriously poisoned patients, vasopressors will be needed. Dopamine and norepinephrine have been used; however, many cases are refractory to dopamine. Because dopamine partially acts by causing catecholamine release from sympathetic nerve terminals, it may lose some of its effectiveness when norepinephrine stores are depleted as a result of CA poisoning. Norepinephrine has been demonstrated to have greater efficacy than dopamine in successfully treating refractory hypotension (6). Dosing of norepinephrine should start at 0.04 μg/kg/min and be titrated up as needed to a mean arterial pressure of 60 mm Hg. In patients unresponsive to these measures, bedside or formal echocardiography, pulse-contour analysis to determine cardiac output and systemic vascular resistance, or the

insertion of a pulmonary artery catheter may be useful to guide additional fluid and vasopressor management.

For patients in refractory shock, true extremis or cardiac arrest from CA poisoning, intravenous fat emulsion (IFE or Intralipid) has been successfully used (7). Though the mechanism of IFE is not fully elucidated, the infusion of lipid may create a “lipid sink” in the blood. Fat-soluble drugs diffuse into the lipid sink and away from the deleterious site of action. IFE was initially described and has now become standard care in the resuscitation of patients with local anesthetic overdose in the operating room. Its use subsequently expanded to other cardiotoxic drugs, including CAs (7). Results, however, have been mixed with regard to the use of IFE in CA poisoning. In animals IFE outperformed hypertonic sodium bicarbonate for treating hypotension for clomipramine (8) however was associated with worse survival and higher serum drug concentrations for amitriptyline (9). The differences in these studies may be evidence that IFE is effective for the treatment of poisoning from some CAs but not others. At this time the use of IFE in CA poisoning remains reasonable for the patient in true extremis refractory to sodium bicarbonate, norepinephrine, and usual supportive care. The dose is 1.5 mL/kg of 20% IFE over 2 to 3 minutes, followed by an infusion of 0.25 mL/kg/min over 30 minutes. The bolus dose may be repeated as needed up to two additional doses. As experience increases, the use of IFE may become better defined.

Cardiac dysrhythmias can be terminated with sodium bicarbonate. Sodium and bicarbonate have both proven to be beneficial treatments for toxins that have quinidine-like, sodium-channel blocking actions. In experimental models of amitriptyline toxicity, sodium loading and increasing pH each separately improve cardiac conduction, but both treatments together produced the greatest improvement. Although hypertonic saline, 7.5% in dextran, without bicarbonate dramatically increases blood pressure and narrows the QRS interval after nortriptyline poisoning in animals, hypertonic saline is not widely used in clinical practice. Sodium bicarbonate boluses and normal saline infusions are usually

sufficient but require careful monitoring as overuse can cause severe hypernatremia, fluid overload, and alkalemia.

Dysrhythmias should be treated with at least two or three ampules (100 to 150 mEq, or a dose of 1 to 2 mEq/kg) of sodium bicarbonate. This bolus dosing should occur every 3 to 5 minutes until the QRS narrows; this dosing scheme can result in large doses of bicarbonate administration. Sodium bicarbonate has acutely terminated VT and wide-complex tachycardia. The QRS duration shortens, and the terminal 40-ms changes become less evident. Respiratory alkalosis is advocated by many clinicians, but the pH increase is not as instantaneous as with bolus bicarbonate administration, and sustained respiratory alkalosis will lead to compensatory renal bicarbonate excretion, resulting in a relative deficiency state. The target pH for alkalinization is 7.45 to 7.55, but caution is needed to avoid overshooting the desired pH or causing hypernatremia or ionized hypocalcemia. In addition, the administration of large amounts of bicarbonate for a number of hours may lead to respiratory acidosis and hypoventilation in the nonintubated patient.

Dialysis is not helpful because of high protein-binding and the large volume of distribution.

Because in overdose, CAs are, epileptogenic and benzodiazepines can be therapeutic, the use of flumazenil is in general contraindicated for patients with coma and a history or ECG suggestive for moderate or severe CA poisoning. Anticholinergic delirium is common in moderate TCA poisoning, and physostigmine has been effective in reversing anticholinergic toxicity. The use of physostigmine in CA poisoning is controversial. Because of case reports of asystole after physostigmine use in unstable CA-poisoned patients, physostigmine was avoided for many years. It was contraindicated for patients with a prolonged QRS interval or dysrhythmias suggestive of CA cardiotoxicity. More recently, one center reported uncontrolled use of physostigmine for delirium and coma with improvement in 236 of 252 retrospective and 62 of 63 prospective CA-poisoned patients. No patients in either arm suffered significant ventricular dysrhythmias or asystole (10). While

physostigmine may improve delirium, coma, or agitation from the anticholinergic syndrome in those not critically ill, it is unclear if this surpasses routine intensive care. Care must be taken to administer physostigmine over 3 to 5 minutes since an IV push bolus is associated with seizures and bradycardia. Concomitant use of benzodiazepines is recommended. Benzodiazepines alone do not effectively control anticholinergic delirium unless heavily sedating doses are used, which may extend the length of stay and increase complications and intubations.

Gastrointestinal decontamination should be accomplished after the institution of any necessary life-support measures. AC in a dose of 1 g/kg is the method of choice for gastric decontamination, when safe to administer. Multiple doses of AC have not been of clinical benefit and are not recommended. Care should be taken to avoid aspiration of charcoal into the lung, which can dramatically prolong hospital stays. Though no longer routinely recommended for most poisonings, gastric lavage, may benefit some early presenting (within 1 to 2 hours) CA-poisoned patients because the toxicity of this overdose is so high.

CRITICAL INTERVENTIONS

- Establish IV access and initiate continuous cardiac and oxygen saturation monitoring.
- Administer benzodiazepines quickly and aggressively for seizures to avoid increasing acidosis.
- Use sodium bicarbonate at 1 to 2 mEq/kg IV every 3 to 5 minutes for dysrhythmias and cardiac conduction disturbances >100 ms.
- Administer intravenous fluids and norepinephrine for hypotension.
- Administer propofol or phenobarbital for refractory seizures or myoclonus.

DISPOSITION

The maximal severity of CA poisoning is usually apparent within 2 to 6 hours of an overdose. Patients who develop coma, hypotension, seizures, or dysrhythmias require intensive care unit admission. Those who remain or become asymptomatic including lack of sinus tachycardia after 6 hours of observation can be medically cleared for discharge or psychiatric evaluation. Patients with persistent but mild symptoms, such as lethargy or tachycardia, require additional monitoring and observation in emergency department (ED) observation units or intermediate care units are appropriate.

If critically ill and complicated poisoned patients are transferred, either an air ambulance or an advanced cardiac life-support–equipped crew, accompanied by a nurse or physician, is required to treat ongoing complications.

Common Pitfalls

- Failure to appreciate that awake and stable-appearing patients with recent CA overdose may rapidly deteriorate.
- Failure to recognize the subtle electrocardiographic changes consistent with CA poisoning.
- Failure to wait for conduction delay or wide QRS before starting bicarbonate therapy.
- Failure to aggressively prevent and treat seizures and correct the resultant metabolic acidosis.

ACKNOWLEDGMENTS

The author would like to thank William J. Cimikoski and Keith K. Burkhart who contributed to this chapter in previous editions.

CHAPTER 340

Dystonic Reactions

Jennifer Cullen and Richard F. Clark

Dystonic reactions are seldom life-threatening, but the discomfort of the bodily contortions and panic that can develop prompt the victim to seek help in the emergency department (ED).In addition, iatrogenic dystonic reactions and *akathisia* are common with the administration of antiemetic and antipsychotic medications in the ED. These effects appear early and are reversible with reduction or discontinuation of the offending agent. *Tardive dyskinesia* refers to the sometimes irreversible involuntary movements that develop later and results from withdrawal of the antipsychotic agent. *Primary dystonia,* abnormal movements that occur spontaneously in the absence of drug treatment, is a separate neurologic diagnosis with similar manifestations. Dystonias may begin at any age, for both the primary and secondary or drug-induced types (1).

Dystonias of all types likely result from an abnormality in neurotransmitter function in the basal ganglia. Proposed mechanisms include (a) direct blockade of central dopaminergic receptors, (b) an imbalance of dopamine and acetylcholine, resulting in excessive cholinergic activity, and (c) a combination of dopamine blockade and dopamine activation in the nigrostriatal system (2). Dopamine synthesis and release increase in response to an initial blockade of dopamine receptors. A single dose of an antipsychotic drug increases the sensitivity of dopamine receptors for 24 to 48 hours after drug administration. This occurs at a time when plasma and red blood cell drug concentrations are usually falling. Therefore, enhanced dopamine release, occurring

simultaneously with the unblocking of supersensitive receptors, may result in acute dystonias.

The true prevalence of acute dystonic reaction is unknown, but is estimated to occur in 2.3% to 60% of patients treated with typical antipsychotic agents, and 2% to 3% of patients treated with atypical antipsychotics (3). Most acute dystonic reactions occur within 5 days of starting therapy with neuroleptics and are more common in men than in women. Although less common, dystonias have been reported with other neurologic agents such as lamotrigine (4).

Symptoms seem to develop earlier with haloperidol than other neuroleptics. The development of a dystonic reaction depends more on individual susceptibility than on the chemical structure, milligram potency, dosage, or duration of treatment. The drugs currently known or suspected to produce acute dystonic reactions are listed in Table 340.1.

TABLE 340.1
Drugs Reported or Suspected to have Caused Acute Dystonic Reactions

Generic Name	Trade Name	Generic Name	Trade Name
Albendazole		Loxapine	Loxitane
Amitriptyline	Elavil	Mesoridazine	Serentil
Amoxapine	Asendin	Methohexital	Brevital
Aripiprazole	Abilify	Methylphenidate	Ritalin
Azatadine	Optimine	Metoclopramide	Reglan
Bupropion	Zyban, Wellbutrin	Nefazadone	Serzone
Cetirizine	Zyrtec	Olanzapine	Zyprexa
Chlorpromazine	Thorazine	Ondansetron	Zofran
Chlorprothixene	Taractan	Paroxetine	Paxil
Chloroquine		Perphenazine	Trilafon
Cimetidine	Tagamet	Phenelzine	Nardil
Cisapride	Propulsid	Phenytoin	Dilantin
Cocaine		Pimozide	Orap
Clomipramine	Anafranil	Prochlorperazine	Compazine
Clozapine	Clozaril	Promazine	Sparine
Cyclizine	Marezine	Promethazine	Phenergan
Dextrometho-rphan		Propofol	Diprivan
		Quetiapine	Seroquel
Diazepam	Valium	Quinine	
Diphenhydramine	Benadryl	Ranitidine	Zantac
Diprivan	Propofol	Risperidone	Risperdal
Doxepin	Sinequan	Rivastigmine	Exelon
Etomidate	Amidate	Sertraline	Zoloft
Fentanyl		Thiethylperazine	Torecan
Fluoxetine	Prozac	Thiopental	Pentothal
Fluphenazine	Prolixin	Thioridazine	Mellaril
Fluvoxamine	Luvox	Thiothixene	Navane
Foscarnet	Foscavir	Tiagabine	Gabitril
Gabapentin	Neurontin	Tranylcypromine	Parnate
Haloperidol	Haldol	Trifluoperazine	Stelazine
Imipramine	Tofranil	Triflupromazine	Vesprin
Ketamine	Ketalar	Ziprasidone	Geodon
Lamotrigine	Lamictal		

Although also seen in the elderly, patients younger than age 15, those with a family history of dystonia, and a history of drug or alcohol use are at greatest risk of developing drug-induced dystonias (5).

Akathisia is an uncomfortable condition of motor restlessness and agitation that occurs in association with the same drugs that induce dystonic reactions and probably with the same pathophysiology. Prochlorperazine (Compazine), commonly used as an antiemetic and for the treatment of migraine, frequently induces akathisia. When patients are carefully monitored for signs and symptoms, prochlorperazine may induce akathisia in up to 44% of patients within 1 hour of administration and, in a few percent more, in a delayed fashion up to 48 hours later (6). The rate of IV administration (15-minute infusion vs. 2-minute bolus) does not appear to significantly affect the incidence of akathisia. The use of adjuvant diphenhydramine (50 mg IV) in association with prochlorperazine (10 mg IV) reduces the incidence of akathisia from 36% to 14% in one study but also causes more sedation (7). Akathisia and dystonia are rarely reported with ondansetron (8).

CLINICAL PRESENTATION

Any striated muscle group may be involved in a dystonic movement. Blepharospasm, progressing to *oculogyric crisis,* is the most common form of dystonia in the upper face. It usually begins with increased blinking of the eyelids. In the lower face, the muscles of the pharynx and tongue are most commonly involved. *Oromandibular dystonia* describes the involvement of any combination of the jaw muscles. Specifically, *mandibular dystonia* is manifested as a pulling down or up of the jaw, and *lingual dystonia* is either a sustained protrusion of the tongue or an upward deflection so that the tongue curves and touches the hard palate. In the neck, *torticollis* is most common, although retrocollis and anterocollis may also occur. In most cases, the shoulder is elevated on the side toward which the chin is pointing. Jerking, rhythmic movements of the head may also occur. When the trunk is involved, twisting movements and postures such as lordosis, scoliosis, kyphosis, tortipelvis, and opisthotonos develop. Dystonic movements may begin focally but become segmental as they spread in a contiguous manner. *Generalized dystonia* refers to involvement of the leg plus other body parts, with

or without the trunk. Dystonic movements are usually continual, repetitive, and twisting, varying in speed from rapid to slow and being sustained from seconds to minutes at the height of the involuntary contraction.

The prognosis is excellent for patients with drug-induced dystonias when promptly and correctly treated. While the symptoms can result is significant distress and anxiety, the vast majority of patients will improve with treatment. Though rare, cardiorespiratory arrest and death have been reported in acute drug-induced laryngeal dystonia (2).

DIFFERENTIAL DIAGNOSIS

Dystonic reactions have been misdiagnosed as generalized anxiety, hysterical conversion, tetanus, and even seizure disorders. Children with such abnormal movements have been thought to have encephalitis or meningitis (9). Strychnine poisoning and the choreiform movements sometimes seen with sympathomimetic abuse ("crack dancing") or with rheumatic fever may appear similar to dystonic reactions as well. Some rigid patients with serotonin syndrome may also appear dystonic.

Patients taking antipsychotic agents are also at risk for neuroleptic malignant syndrome (NMS), which presents with muscle rigidity that may be mistaken for a dystonic reaction. It is critical to distinguish this life-threatening condition from acute dystonia. For further discussion of NMS, please see Chapter 338.

ED EVALUATION

The patient, family, or friends should be asked about the recent use of medications. Physical examination is remarkable for typical abnormal posturing or movements. Response to antimuscarinic treatment supports the diagnosis.

KEY TESTING

- There is no relevant laboratory or imaging testing for dystonic reactions.

ED MANAGEMENT

As dystonic reactions are not usually associated with an acute drug overdose, gastrointestinal decontamination is not necessary. Administration of an antimuscarinic medication rapidly reverses the symptoms of dystonia in most cases, presumably because of restoration of the cholinergic–dopaminergic balance in nigrostriatal neurons. Diphenhydramine (Benadryl) and benztropine mesylate (Cogentin) are the two medications most frequently used. IV administration is preferable to IM or oral administration and symptoms typically abate within 2 minutes and completely resolve within 15 minutes when the IV route is used. Muscle relaxation begins within 30 minutes but may not be complete for 90 minutes when the treatment is given IM or orally. Benztropine has been advocated over diphenhydramine because of less sedation and more rapid improvement of both objective and subjective findings, regardless of route of administration. Diphenhydramine should be used in children younger than age 3, as the greater antimuscarinic effects of benztropine are considered contraindicated in children this age, who may be more sensitive. Drowsiness should be anticipated as a side effect of antimuscarinic drug administration, especially with diphenhydramine.

After reversal of the reaction, some clinicians advocate an oral agent be continued for 72 hours to prevent a relapse (10). However, extended therapy may not be needed in all cases.

The usual dose of benztropine is 1 to 2 mg for adults and 0.02 to 0.05 mg/kg for children age 3 years or older, given IV over 2 minutes, followed by the same dose orally twice a day for 3 days if needed. The dose of diphenhydramine is 50 to 100 mg for adults and 1 to 2 mg/kg for children, given IV over 2 minutes, followed by 12.5 to 50.0 mg orally three or four times a day for 3 days if needed. Some patients may require more than one dose of IV medication to control the reaction.

Rare cases of dystonia may not respond to antimuscarinic therapy, and benzodiazepines should be used as a second-line agent. Unlike diphenhydramine and benztropine, side effects from the

benzodiazepines are limited to drowsiness. Antimuscarinic sequelae such as dry mouth, blurred vision, and urinary retention are not expected. Although any benzodiazepine should be effective, diazepam and lorazepam are favored because of their longer duration of action. Diazepam can be administered IV in 5-mg increments every 5 minutes as needed for reversal, or lorazepam 2 mg IV may be given every 5 minutes as needed.

Prophylactic use of benztropine and diphenhydramine has reduced the incidence of dystonic reactions in patients receiving either antiemetic or antipsychotic medications (10). Sedation may be increased, however, and should be considered.

CRITICAL INTERVENTIONS

- Recognize acute dystonia as an adverse drug reaction rather than another medical or psychiatric disorder.
- Treating dystonic reactions with antimuscarinic medications, such as benztropine or diphenhydramine, can be diagnostic and therapeutic.
- Prescribe oral antimuscarinic medication for 3 days after acute treatment to prevent relapse.

DISPOSITION

The patient may be discharged after the acute dystonia resolves. Notifying the prescribing psychiatrist may be advisable if the patient is to remain on neuroleptic medication. When antimuscarinics are prescribed, patients should be advised not to drive or perform potentially dangerous activities for 72 hours. They should be instructed to return if symptoms recur.

Common Pitfalls

- Dystonic reactions may be delayed 12 to 24 hours from the time of drug ingestion.
- Dystonic reactions are not usually from an overdose; so gastrointestinal decontamination is seldom indicated and may be dangerous in patients with head or neck involvement.

CHAPTER 341

Lithium

Fiona M. Garlich

Lithium has been used in the management of depression and bipolar disorders for over 50 years (1). In the United States, lithium is available as both immediate- and sustained-release formulations. Because lithium has a narrow therapeutic index and numerous adverse effects, relatively small changes in dose or health status can result in toxicity in patients on chronic lithium therapy. The therapeutic serum concentration is generally cited as 0.6 to 1.2 mEq/L (mmol/L).

Understanding the kinetics of lithium is important for the proper management of patients with lithium overdose. Immediate-release preparations are rapidly and completely absorbed from the gastrointestinal (GI) tract, with peak serum concentrations seen at 1 to 2 hours (2). Delayed absorption may occur in large overdoses, in the presence of coingestants that slow gastric emptying, or with the ingestion of sustained-release preparations. Delayed peak serum concentrations have been reported from 18 to 72 hours following large overdoses of sustained-release lithium tablets (1,3,4).

Following absorption from the GI tract, lithium, as a charged ion, is distributed slowly into tissues, especially across the lipophilic blood–brain barrier. The final volume of distribution is 0.6 to 0.9 L/kg, equivalent to that of total body water (1). After an acute overdose, the patient may initially appear well with a high serum concentration, but then may deteriorate as lithium distributes from the blood to the brain. The serum concentration may actually decrease while levels in the brain rise.

Lithium is eliminated almost entirely by renal excretion. The renal handling of lithium is similar to that of sodium; it is filtered and reabsorbed by the proximal tubule. Toxicity is more likely in the setting of dehydration, hyponatremia, decreased sodium intake, renal compromise, and the use of thiazide diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), or angiotensin-converting enzyme (ACE) inhibitors (5). Lithium itself can be nephrotoxic and may result in renal insufficiency (1). Chronic lithium therapy can also induce nephrogenic diabetes insipidus which can lead to dehydration, resulting in toxicity even without a change in dosage.

CLINICAL PRESENTATION

Lithium is primarily a neurotoxin, and poisoning can result in tremor, fasciculations, hyperreflexia, rigidity, clonus, nystagmus, ataxia, and in more severe toxicity, altered mental status, coma, seizures, and death (1,5,6). See the clinical classification in Table 341.1 (6). It is useful to classify an overdose as (1) acute (single ingestion), (2) acute-on-chronic (overdose in the setting of chronic therapy), or (3) chronic. In acute toxicity, nausea, vomiting, and diarrhea may predominate early on, with the late development of neurologic symptoms. Neurotoxicity with gradual deterioration is the predominant finding in chronic poisoning, which can occur in patients who develop dehydration or renal insufficiency even without a change in dosage. Greatest toxicity is seen in patients with chronic and acute-on-chronic overdoses, who have prolonged exposure to high-tissue lithium concentrations. In this setting, permanent neurologic sequelae can result and aggressive interventions are warranted (7).

TABLE 341.1
Severity of Lithium Poisoning

Grade 1 (mild): Nausea, vomiting, tremor, hyperreflexia, agitation, muscle weakness, ataxia

Grade 2 (moderate): Confusion, dysarthria, rigidity, hypertonia, hypotension, stupor

Grade 3 (severe): Convulsions, myoclonic jerking, coma, cardiovascular collapse

Acute lithium toxicity can also result in electrocardiographic (ECG) changes, including nonspecific ST-segment changes, T-wave flattening or inversion (which may mimic cardiac ischemia), prolongation of the QT interval, and first-degree atrioventricular block (8). Clinically significant dysrhythmias or cardiac dysfunction are rare.

DIFFERENTIAL DIAGNOSIS

The neurologic symptoms of lithium toxicity may closely resemble serotonin syndrome, although hyperthermia and autonomic instability are typically absent. Neuroleptic malignant syndrome (NMS), parkinsonism, and tardive dyskinesia should be considered in patients with rigidity. Neurologic manifestations of lithium toxicity might mimic a cerebrovascular accident, a postictal state, meningitis, hypercalcemia, hyperthyroidism, or toxicity from coingestion of other psychiatric medications such as antipsychotics, antidepressants, carbamazepine, and valproic acid. The common nausea and vomiting seen after an acute overdose may be easily confused with gastroenteritis or food poisoning.

ED EVALUATION

Attention should focus on the patient's mental status and neurologic motor examination, searching particularly for tremor, myoclonus, hyperreflexia, and rigidity. In the patient with chronic motor findings, the presence of worsening and increased disability should be determined. Hydration status, serum electrolytes, and renal function must be assessed. A serum lithium concentration should be obtained, and should be repeated serially in the setting of an acute overdose, particularly with sustained-release preparations. Because of the delay in tissue distribution, neurologic symptoms may lag

behind the serum concentration. Symptoms often worsen after the peak concentration is reached, and clinical improvement may be delayed despite a decreasing concentration. Green-top tubes may contain lithium heparin and should not be used. Testing for coingestants, including acetaminophen, salicylates, and ethanol should be considered in patients with intentional self-poisoning. An ECG should be obtained primarily to check for prolonged QT interval.

KEY TESTING

- Obtain a serum lithium concentration and repeat to determine if rising
- Check serum electrolytes and creatinine
- Obtain an ECG

ED MANAGEMENT

Advanced life-support measures should be instituted as necessary. Aggressive intravenous hydration with normal saline should be performed until euvolemia is achieved, to enhance renal perfusion and increase lithium elimination in dehydrated patients (1,9). Caution should be used in patients who are susceptible to fluid overload. There is no benefit to overhydrating or "forced diuresis" (9).

Whole-bowel irrigation (WBI) with polyethylene glycol should be considered for acute ingestions of sustained-release lithium preparations (9). Activated charcoal does not bind small ions such as lithium and should only be given if significant coingestants are suspected and the airway is protected. Gastric lavage is not likely to be useful, as immediate-release preparations are rapidly absorbed and sustained-release tablets are too large to fit through lavage tubes.

There is experimental evidence that sodium polystyrene sulfonate (Kayexalate), an ion-exchange resin usually used to treat hyperkalemia, can prevent absorption of lithium and enhance its removal once absorbed (9). However, clinical efficacy is unproven

and the development of hypokalemia limits the broad applicability of this technique.

Hemodialysis is the most efficient method of removing lithium from the body. However, redistribution from the brain to the intravascular compartment is slow, and clinical improvement lags behind the fall in serum lithium concentrations (2,10). A significant rebound of the serum lithium concentration usually occurs, which may necessitate a second or third round of dialysis in the sickest patients. Hemodialysis is recommended for patients with severe or progressive lithium toxicity (especially those with significant alterations in mental status or seizure), those with renal failure, and those who cannot tolerate sodium repletion therapy. Serum lithium concentrations do not correlate well with toxicity, and the patient's clinical status is a much better indicator of the need for hemodialysis than a serum concentration. However, by the time a patient is severely toxic, much of the lithium has distributed out of the blood compartment and is not available for removal by dialysis, making late hemodialysis of limited utility. Historical guidelines recommend hemodialysis in any patient with a lithium concentration above 4 mEq/L, or greater than 2.5 mEq/L in chronic toxicity (6). It is important to note that significant toxicity necessitating hemodialysis can be manifested in patients with concentrations below these cutoffs, especially those on chronic therapy. Conversely, young, healthy patients who are asymptomatic after an isolated acute overdose may not need dialysis at all despite lithium concentrations that are quite elevated. Some neurologic symptoms such as tremor or ataxia may persist after the lithium concentration has normalized.

CRITICAL INTERVENTIONS

- Administer normal saline intravenously for rehydration and treatment of hyponatremia.
- Consider early WBI for large ingestions of sustained-release tablets.

- Consider hemodialysis in patients with significant clinical toxicity and high lithium concentrations, and those with renal insufficiency.

DISPOSITION

Patients should be admitted if they have a high or rising lithium concentration, renal failure, dehydration, or significant neurologic findings such as confusion, lethargy, increased tremor, hyperreflexia, or rigidity. The presence of seizure or coma should prompt admission to an intensive care unit. Consultation with a poison center or toxicologist is strongly recommended. Although hemodialysis may not be necessary, early nephrology consultation can result in the dialysis team's being mobilized more quickly when needed. In patients who are asymptomatic following acute ingestions, serial lithium concentrations should be obtained every 4 to 6 hours until they start to fall. Patients who have ingested sustained-release products should be monitored for a minimum of 12 hours to ensure serum concentrations start to fall. In all cases of overdose with suicidal intent, psychiatric consultation should be obtained before discharge.

Common Pitfalls

- Failure to consider the possibility of chronic lithium toxicity in patients taking lithium who develop dehydration, renal compromise, or hyponatremia.
- Failure to obtain serial lithium concentrations in patients with acute overdose, especially with a sustained-release lithium preparation.
- Failure to appreciate that severe lithium poisoning can lead to permanent neurologic impairment and that aggressive treatment is warranted.

CHAPTER 342

Monoamine Oxidase Inhibitors

Diana Felton and Michael J. Burns

The monoamine oxidase (MAO) inhibitors have been used to treat major depression since the 1950s (1) but are infrequently used today because of their risk for producing dangerous food and drug interactions and serious toxicity after overdose. These agents are generally reserved for the management of atypical, drug-resistant, neurotic, or reactive depression and occasionally to treat anxiety states, bulimia, hypertension, migraine headaches, narcolepsy, obsessive–compulsive disorder, attention deficit hyperactivity disorder, tobacco addiction, Parkinson disease, and phobias (1) and most recently, as a possibility for Alzheimer dementia. Newer selective, reversible inhibitors of MAO have a lower propensity for adverse effects (1,2,3). All of these agents block MAO, the oxidative deamination of endogenous and exogenous monoamines, in the outer mitochondrial membranes of most tissues (1). The two subtypes of MAO (MAO-A and MAO-B) differ in their substrate and inhibitor specificities and tissue distribution (1,2,4). MAO-A is found in the brain (monoaminergic neurons), peripheral sympathetic postganglionic neurons, intestinal mucosa, and liver. MAO-B is located in the brain (glial cells and some serotonergic neurons), platelets, liver, and intestinal mucosa (1).

Noradrenergic neurons contain predominantly MAO-A; serotonergic neurons contain both MAO-A and MAO-B. Inhibition of MAO-A is necessary for the treatment of depression (1). MAO enzymes function to maintain low body concentrations of

monoamines (1,2,5). Hepatic and intestinal MAOs prevent the absorption of and systemic effects from dietary monoamines (e.g., tyramine) (1).

All MAO inhibitors are false substrates for the MAO enzyme and bind competitively to the active site of MAO and prevent further activity (1). MAO inhibitors may be classified by their differential selectivity for MAO subtypes, reversibility of MAO binding (inhibition), or by chemical structure (Table 342.1).

TABLE 342.1
Classification of Monoamine Oxidase Inhibitors

Agent (Trade Name)	Inhibition	Selectivity	Structure
Befloxatone	Reversible	MAO-A	Oxazolidinone
Brofaromine	Reversible	MAO-A	Piperidylbenzofuran
Clorgyline	Irreversible	MAO-A	Acetylenic agent
Furazolidone (Furoxone)	Reversible	Nonselective	Oxazolidinone
Iproniazid (Marsilid)	Irreversible	Nonselective	Hydrazine (Hydrazide)
Isocarboxazid (Marplan)	Irreversible	Nonselective	Hydrazine (Hydrazide)
Linezolid (Zyvox)	Reversible	Nonselective	Oxazolidinone
Moclobemide (Aurorix)	Reversible	MAO-A	Benzamide
Nialamide (Niamid)	Irreversible	Nonselective	Hydrazine
Pargyline (Eutonyl)	Irreversible	MAO-B	Acetylenic agent
Phenelzine (Nardil)	Irreversible	Nonselective	Hydrazine
Procarbazine (Matulane)	Irreversible	Nonselective	Hydrazine
Rasagiline (Azilect)	Irreversible	MAO-B	Acetylenic agent
Selegiline, l-deprenyl (Eldepryl, Emsam)	Irreversible	MAO-B	Acetylenic agent
Toloxatone (Humoryl)	Reversible	MAO-A	Oxazolidinone
Tranylcypromine (Parnate)	Irreversible	Nonselective	Cyclopropylamine

Currently, only irreversible inhibitors of MAO are available in the United States (1). Nonselective inhibitors include isocarboxazid, phenelzine sulfate, and tranylcypromine sulfate. Selegiline and rasagiline are selective inhibitors of MAO-B used to treat Parkinson disease (1,6). They are not associated with dangerous food and drug

interactions at doses used clinically (1,3). Their specificity for MAO-B, however, is dose dependent and lost at supratherapeutic doses (1,3). Selegiline (Emsam) is approved and available as a transdermally delivered patch, as well as a transmucosal dissolving lozenge (7). The dangerous food interactions (as occurs from ingested monoamines) are less likely with cutaneous MAO inhibitor delivery that does not readily inhibit intestinal and hepatic MAO (3,7). Certain pharmaceuticals (e.g., furazolidone, linezolid, procarbazine) and herbal preparations (e.g., St. John's Wort, yohimbe alkaloids, kava kava, and ayahuasca) also have MAO inhibitor activity (1,6). These agents are all weak, reversible, nonselective inhibitors of MAO but still have the potential for adverse drug and food interactions.

Reversible selective inhibitors of MAO-A (befloxatone, brofaromine, cimoxatone, moclobemide, and toloxatone) are used outside the United States (1,2). With these agents, MAO inhibition is short-lived (enzyme activity commonly restored within 24 hours) and may be overcome by increasing levels of amine substrate. Initial experience with these agents has demonstrated greater safety after overdose and a significant reduction of adverse effects when combined with other pharmaceutical agents or dietary amines (1,2,3).

Most MAO inhibitors are structurally similar to amphetamines and other sympathomimetic agents; in fact, both selegiline and tranylcypromine are partly metabolized to amphetamine and methamphetamine (1,8,9). MAO inhibitors exert their pharmacologic and toxic effects by decreasing the degradation of MAO substrates, MAO inhibitors result in expansion of cytosolic and vesicular storage of NE, DA, and 5-HT in presynaptic nerve terminals (Fig. 342.1). This subsequently increases their release from vesicles during normal neurotransmission, causes spontaneous spillover into the synaptic cleft independent of nerve activity, and decreases concentration-dependent reuptake by nerve-ending amine transporters (1,2). Spontaneous hypertensive episodes with therapeutic doses of MAO inhibitors are likely a result from spontaneous release of NE from nerve terminals (4,9). MAO inhibitors further enhance the release of

cytoplasmic amines from the nerve ending in the absence of vesicle exocytosis (1,9). They bind competitively to the amine uptake transporter and prevent reuptake of natural amine neurotransmitters. When the MAO inhibitor is transported into the neuron, reverse transport of cytosolic biogenic amines occurs that further increases their synaptic concentrations. MAO inhibitors similarly prevent uptake from glial cell transporters that scavenge extracellular (synaptic) monoamines (1,2).

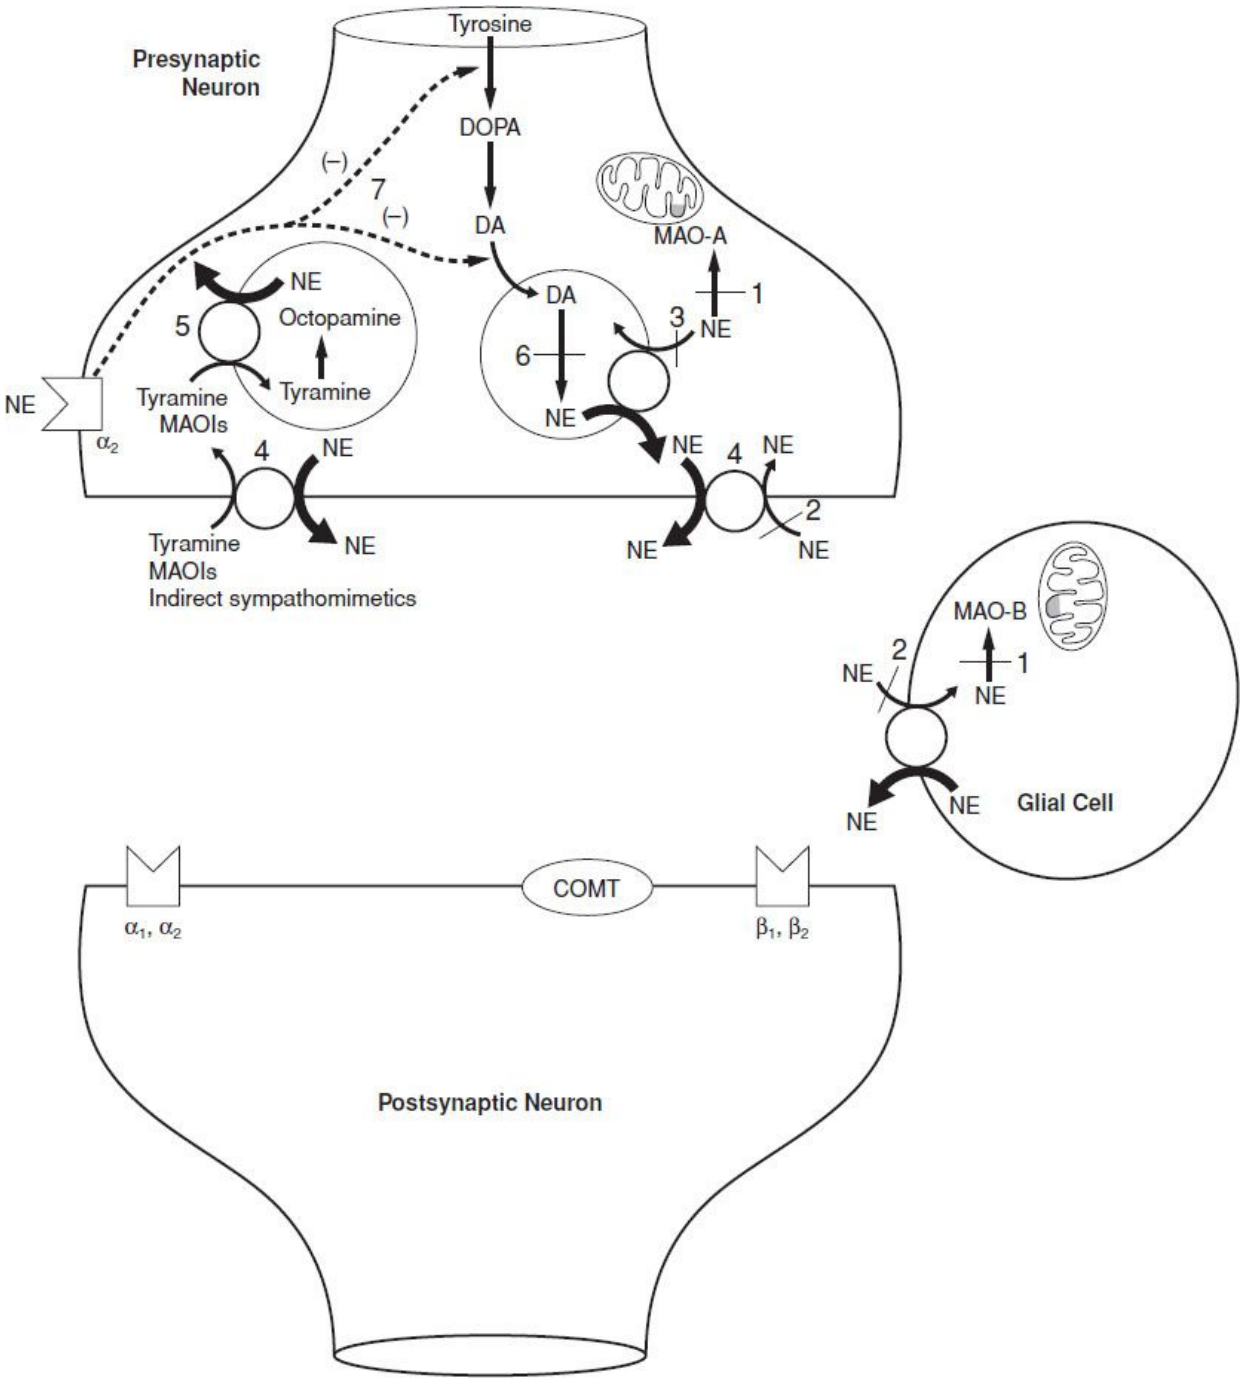

FIGURE 342.1 Diagram of a noradrenergic synapse illustrating the mechanisms underlying monoamine oxidase inhibitor (MAOI) toxicity: (1) Inhibit MAO to prevent norepinephrine (NE) degradation; (2) inhibit NE reuptake by monoamine transporter; (3) inhibit NE reuptake by vesicles; (4) promote reverse transport of NE from nerve ending; (5) promote reverse transport of NE from vesicles; (6) block dopamine (DA) β-hydroxylase; (7) indirectly

inhibit enzymes necessary for production of NE. Similar mechanisms operate at dopaminergic and serotonergic nerve endings (α- and β-adrenergic receptors; COMT, catechol-o-methyltransferase, another enzyme that degrades catecholamines.)

Overdose of MAO inhibitors produces an exaggeration of these neuronal effects resulting in profound hyperadrenergic, hyperdopaminergic, and hyperserotonergic states. The delay of signs and symptoms after overdose is due to initial reversible binding with MAO and the time required for significant enzyme inhibition and cumulative effects to occur (e.g., neuronal accumulation of NE, DA, 5-HT) (1,4,9). The neuromuscular abnormalities (e.g., rigidity, myoclonus), hyperthermia, and unusual ocular movements associated with MAO overdose appear to be mediated primarily by enhanced serotonergic neurotransmission in the brainstem and spinal cord. Stimulation of 5-HT1 A receptors from raphe bulbospinal neurons results in myoclonus and rigidity. These neuromuscular effects combined with stimulation of 5-HT2 receptors in the diencephalon result in hyperthermia. Enhanced raphe serotonergic neurotransmission, which controls saccadic eye movements, may produce an unusual “ping-pong” gaze in patients with severe MAO inhibitor toxicity (5). These effects are also seen in the serotonin syndrome (Chapter 343).

The most serious adverse reactions associated with drug and food interactions are also the result of exaggerated neuronal effects (3,6). The administration or ingestion of any agent that increases CNS dopamine, norephinephrine, or serotonin levels may result in potentially life-threatening toxicity (1,3,6). Enhanced serotonergic neurotransmission, known as the serotonin syndrome (see Chapter 343, Serotonin Re-uptake Inhibitors and the Serotonin Syndrome), occurs when MAO inhibitors are combined with agents that enhance serotonin synthesis (e.g., *L*-tryptophan), promote serotonin release (e.g., methylenedioxymethamphetamine, fenfluramine, tramadol), or block serotonin reuptake (e.g., selective serotonin reuptake inhibitors, tricyclic antidepressants, lithium, phenylpiperidine, meperidine, dextromethorphan, propoxyphene, methadone) (1,3,6).

Indirectly acting sympathomimetic agents (e.g., amphetamine, cocaine, synthetic cathinones ("bath salts"), ephedrine, phenylpropanolamine, methylphenidate) act primarily by causing the release of NE from the presynaptic nerve terminal, resulting in the release of the expanded pool of NE to cause signs and symptoms of catecholamine poisoning (hypertensive crisis) (4,6,9).

A similar sympathomimetic effect, called the "cheese reaction," may occur when food containing tyramine (e.g., aged cheeses; aged, pickled, or smoked meats; certain beers; red wines; and yeast extracts) and other indirectly acting monoamines (e.g., ephedrine, phenylethylamine, phenylethanolamine, pseudoephedrine, octopamine, reserpine, and tryptamine) are ingested (3,6). Inhibition of MAO in the liver and intestine allows for systemic absorption of these amines which may precipitate a rapid, massive release of NE when taken up into noradrenergic nerve endings.

MAO inhibitors are rapidly and completely absorbed, with peak plasma concentrations 1 to 4 hours after ingestion (1,8,9). For irreversible MAO inhibitors, plasma drug concentrations do not correlate with level of MAO inhibition (4,9) and maximal inhibition of MAO occurs after 5 to 10 days of therapy (1,8) and the potential for drug or dietary interactions may last for 2 to 3 weeks after discontinuation of treatment (4,6). The ingestion of 2 to 3 mg/kg or more of an irreversible MAO inhibitor is potentially life-threatening (4,9), with 4 to 6 mg/kg reported to be fatal (9). For reversible inhibitors, however, maximal MAO inhibition is achieved within a few hours after the first dose but MAO activity is restored within 24 hours after the last dose, and the potential for drug and dietary interactions is much less (1,2).

CLINICAL PRESENTATION

Drug or food interactions with MAO inhibitors are common, with hypertensive crisis in 1% to 8% of those taking MAO inhibitors therapeutically (1,4). The clinical presentation includes headache, hypertension, tachycardia (or reflex bradycardia), diaphoresis, agitation, hypertonicity, hyperreflexia, myoclonus, rigidity, seizures, coma, hyperthermia, intracranial hemorrhage, and death. Toxicity

begins within 30 to 90 minutes of the ingestion or administration of sympathomimetic amines (1). The duration of effect is variable but often resolves within a few hours.

MAO inhibitor overdose follows a completely different time course (5,9,10). The absence of early symptoms is typical with nonselective irreversible agents. Onset of toxicity is usually delayed 6 to 12 hours after overdose, peaks in 24 to 48 hours for severe cases, and may last for 72 to 96 hours (9). A latent period as long as 29 hours has been described after tranylcypromine overdose (1). During the latent phase, the patient usually appears well or mildly sedated (1,9,10). Classic symptoms include alterations in behavior, cognition, autonomic nervous system function, and neuromuscular activity and may be classified as mild, moderate, or severe (Table 342.2) (9). Signs and symptoms vary greatly in their onset, severity, and duration. Patients with early or mild toxicity may demonstrate mild lethargy or restlessness, dysarthria, nausea, headache, ataxia, palpitations, flushing, shivering, sweating, tremor, nystagmus, incoordination, or hyperreflexia. Moderate toxicity includes confusion, hallucinations, disorientation, agitated delirium, mutism, salivation, diarrhea, marked diaphoresis, myoclonus, fasciculations, trismus, writhing movements, and mild to moderate elevations of temperature, pulse, respiratory rate, and blood pressure. Severe toxicity is characterized by unresponsive coma; fixed, dilated pupils; “ping-pong” gaze; pathologic reflexes; generalized rigidity; seizures; hyperthermia (>104°F); marked tachypnea or respiratory depression; extreme sinus tachycardia or bradycardia; malignant cardiac dysrhythmias; hypotension; and death (1,5,9,10). Death from cardiovascular (CV) collapse is most likely in patients with severe hyperpyrexia (9,10).

TABLE 342.2
Clinical Course of Monoamine Oxidase Inhibitor Poisoning

Phase-Severity[a]	Time after Ingestion[a]	Cognitive–Behavioral Dysfunction	Autonomic Dysfunction	Neuromuscular Dysfunction
0-Latent	0–24 hrs	Mild lethargy	Absent	Absent
I-Mild	6–12 hrs	Mild lethargy	Nausea	Mild tremor
		Dysarthria	Flushing	Hyperreflexia
		Ataxia	Diaphoresis	Incoordination
		Headache	Shivering	Nystagmus
		Anxiety	Irritability	Mydriasis
		Insomnia		
II-Moderate	10–24 hrs	Confusion	Mild hyperthermia (temperature <104°F)	Myoclonus
		Disorientation	Marked diaphoresis	Fasciculations
		Agitated delirium	Salivation	Trismus
		Mumbling/rambling speech	Piloerection	Facial grimacing
		Mutism	Hypertension	Writhing extremities
		Hyperactivity	Sinus tachycardia (P <150 beats/min)	
			Hyperventilation	
III-Severe	16–72 hrs	Incomprehensible speech	Hyperventilation to respiratory arrest	Generalized rigidity
		Coma	Extreme sinus tachycardia to sinus bradycardia	Opisthotonus
		Seizures	Malignant dysrhythmias (VT, VF, bradyasystole)	Fixed, dilated pupils
			Hypotension	"Ping-pong" gaze
			Pale, clammy, mottled skin	Pathologic reflexes (decorticate, decerebrate, Babinski)
			Severe hyperthermia (temperature <104°F)	
IV-Complications	24–96 hrs	Aspiration pneumonitis	Anion gap metabolic acidosis	Rhabdomyolysis
		Adult respiratory distress syndrome	Hemolysis	Acute renal failure
				Disseminated intravascular coagulation
				Hepatic failure

[a]Signs and symptoms vary greatly in their onset, severity, and duration.

Although seizures may occur after MAO overdose, they are rare and can be confused with the neuromuscular hyperactivity produced by these agents (1,10). Secondary complications in patients with moderate to severe toxicity include aspiration pneumonitis, adult respiratory distress syndrome, rhabdomyolysis, acute renal failure, metabolic acidosis, and disseminated intravascular coagulation (DIC) (9). The likelihood of secondary complications (e.g., rhabdomyolysis, DIC) and death is related to the degree and duration of hyperthermia. Patients with severe toxicity can manifest fixed, dilated pupils, posturing, and extensor plantar response, yet make a complete neurologic recovery (1,5,10).

When taken alone, reversible MAO-A inhibitors have a benign course after acute overdose with doses as high as 20.5 g resulting in only mild to moderate toxicity. Large overdose is characterized by mild CNS depression, agitation, tachycardia, hypertension, and mydriasis. Although death is rare after overdose with moclobemide alone, many fatalities have been reported from the serotonin syndrome with moclobemide and other serotonin-potentiating drugs

(e.g., citalopram, clomipramine, methylenedioxymethamphetamine, paroxetine, and sertraline). Chronic use of irreversible nonselective inhibitors has been associated with hyperadrenergic adverse effects similar to the chronic use of amphetamines. These effects include agitation, confusion, hallucinations, hyperhidrosis, hypomania, insomnia, tremors, and seizures (1).

DIFFERENTIAL DIAGNOSIS

Overdose of stimulants such as amphetamine, cocaine, and sympathomimetic (including over-the-counter appetite suppressants) produces a clinical picture similar to the hypertensive reactions associated with MAO inhibitors and dietary and drug monoamines. The clinical presentation of anticholinergic, hallucinogen (e.g., lysergic acid diethylamide, phencyclidine), lithium, salicylate, sympathomimetic (e.g., amphetamines, synthetic cathinones known as “bath salts,” cocaine), and strychnine poisoning may be similar to that of MAO inhibitor overdose. MAO inhibitor toxicity may be confused with the neuroleptic malignant syndrome and withdrawal from alcohol or sedative hypnotic agents. Clinical features of the serotonin syndrome are nearly identical to those after overdose with MAO inhibitors. Medical emergencies such as hypoglycemia, malignant hyperthermia, intracranial hemorrhage, meningitis, encephalitis, pheochromocytoma, septicemia, tetanus, and thyrotoxicosis may present in a similar manner. The history is most useful to narrow the differential diagnosis.

ED EVALUATION

The history should include the time, dose, and duration of exposure; the time of onset, nature, and severity of symptoms; the type of first aid undertaken; and the medical and psychiatric history. Accurate and complete historical data are essential in differentiating the toxic syndromes related to MAO inhibitors. The physical examination should focus on the vital signs and CV and neurologic functions. Except for “ping-pong” gaze, there are no pathognomonic physical findings or laboratory abnormalities. Initial testing for patients with suspected intentional overdose should include electrocardiogram,

acetaminophen and salicylate, and routine serum chemistries. Patients with toxicity may need complete blood count; prothrombin and partial thromboplastin times; creatine phosphokinase, calcium, magnesium, lactate measurement, and a urinalysis for supportive care. Patients with altered mental status should have a bedside fingerstick glucose determination and intervention, as necessary. A lumbar puncture and computed tomography scanning may be appropriate to rule out intracranial hemorrhage, meningitis, and encephalitis.

Toxicology screening has many false positive and false negatives, especially with amphetamines (see Chapter 348, Amphetamines and Stimulants). Drug screening rarely detects MAO inhibitors because of their low concentrations in blood and urine samples (9). Overdose of selegiline or tranylcypromine may produce a false-positive qualitative screen for amphetamines (9). Quantitative MAO inhibitor levels and MAO enzyme activity are not generally available and do not correlate with the severity of poisoning (4,9).

KEY TESTING

- Routine blood or urine tests cannot confirm or rule out toxicity from MAO inhibitors
- Toxicology screens have many false positive and negatives
- For patients with moderate to severe toxicity, supportive care includes measurements of serum chemistries, lactate, magnesium, calcium, creatine phosphokinase, liver function tests, PT and PTT, and a urinalysis
- Electrocardiogram

ED MANAGEMENT

Supportive care is the primary treatment for MAO inhibitor overdose. Advanced life-support measures with glucose, oxygen, naloxone, and thiamine should be considered for patients with altered mental status. Activated charcoal is the preferred method of GI decontamination for recent MAO inhibitor overdose. Before any

drug or food is given, the potential for an adverse interaction with MAO inhibitors must be considered.

Agitation, neuromuscular hyperactivity, and seizures should be treated promptly with liberal doses of benzodiazepines (e.g., diazepam, lorazepam) or barbiturates (e.g., phenobarbital) (9). Phenytoin is unlikely to be effective for seizures. Pyridoxine is recommended for seizures that occur after overdose with a hydrazine MAO inhibitor.

Rapid cooling is essential to minimize morbidity and mortality. Because hyperthermia is almost invariably associated with CNS agitation and neuromuscular hyperactivity, initial treatment with benzodiazepines or barbiturates is recommended in conjunction with evaporative and convective cooling methods, such as wet sheets or cool mist sprays and fans (9). Antipyretics and cooling blankets are ineffective. If these initial maneuvers do not provide rapid patient cooling, neuromuscular paralysis is strongly recommended (5,9,10) with cooling times of <1 hour. Although dantrolene (2.5 mg/kg orally or intravenously every 6 hours) has been reported to be effective, it is itself toxic and does not terminate muscular rigidity and hyperthermia as rapidly as paralyzing agents. Because the pathophysiology of serotonin syndrome overlaps with MAO inhibitor overdose, nonspecific serotonin receptor antagonists (e.g., cyproheptadine, methysergide) could be of theoretical benefit but without clinical data in this regard, such therapy cannot currently be recommended.

Severe hypertension may be treated with rapid-onset, short-acting, intravenous agents such as sodium nitroprusside, clevidipine, or phentolamine (4,9). Clevidipine (Cleviprex) is a short-acting, intravenous, dihydropyridine calcium channel blocker that is easy to administer and effective for rapid control of severe hypertension. It is given without a bolus starting at 1 to 2 mg/hr and doubled every 90 seconds until the blood pressure improves. Phentolamine (2 to 10 mg IV) is attractive because it blocks α-adrenergic receptors and antagonize the effects of NE. It is effective for the treatment of hypertension associated with the cheese reaction. Dexmedetomidine is a parenteral, titratable, selective, α_2-adrenergic agonist, but the

lack of published data precludes a recommendation. Long-acting agents (tolazoline, clonidine) can worsen the severe hypotension that often follows the hypertension (9). Unopposed α-adrenergic vasoconstriction with β-adrenergic antagonists can exacerbate the hypertension.

Hypotension should be treated with fluid resuscitation. When pressors are required, direct-acting agents (e.g., epinephrine, NE) are recommended (4,9). Indirectly acting agents such as dopamine, require the release of intracellular amines for their pressor effect which may either precipitate a hypertensive crisis or be ineffective with depleted stores of endogenous catecholamines (1). Additionally, MAO inhibition is less likely to potentiate the effects of exogenously administered, direct-acting pressors, which circulate extracellularly and are primarily metabolized by catechol-o-methyltransferase. Regardless, low doses of direct-acting pressors should be used initially to minimize the risk of an exaggerated pressor response. Phenylephrine has been associated with an exaggerated pressor response and is not recommended for MAO inhibitor poisoning.

Ventricular dysrhythmias and severe bradycardias, usually premorbid signs, should be treated according to current advanced cardiac life-support protocols.

Diuresis, urinary acidification, hemodialysis, and hemoperfusion have no role in the management of MAO inhibitor poisoning (1,4,8).

CRITICAL INTERVENTIONS

- Admit all patients with known or suspected MAO inhibitor overdose for 24-hour monitoring even if they have no initial symptoms.
- Treat neuromuscular hyperactivity with benzodiazepines or barbiturates; with neuromuscular paralysis if severe or accompanied by hyperthermia or rhabdomyolysis
- Rapidly and aggressively cool patients with hyperthermia.
- Administer a direct-acting pressor (e.g., norepinephrine) for hypotension unresponsive to fluid administration.

DISPOSITION

All patients with suspected MAO inhibitor overdose should be admitted for extended observation (24 hours) in a monitored setting. Symptomatic patients and those with abnormal vital signs should be admitted to an intensive care unit or transferred to an institution with this capacity.

Patients who present with drug or dietary interactions may not require hospital admission if the clinical response has been mild. Patients with severe reactions, any disorientation, hyperthermia, persistent symptoms, or abnormal vital signs after a 4- to 6-hour observation period, and those with symptoms that necessitate active intervention should be admitted. The level of in-hospital care required (intensive care or floor) depends on the severity of symptoms. For patients well enough to eat, an MAO inhibitor diet (e.g., low tyramine) should be ordered.

Common Pitfalls

- Failure to check for or recognize MAO inhibitor use before prescribing sympathomimetics or giving pain medications, particularly meperidine.
- Failure to appreciate that the history is key to differentiating acute overdose from drug and food interactions, including the serotonin syndrome.
- Failure to appreciate that the onset of toxicity may be delayed and gradual in onset after MAO inhibitor overdose.
- Failure to anticipate that early sympathetic stimulation may be followed by catecholamine depletion and CV collapse in patients with acute MAO inhibitor overdose.

CHAPTER 343

Serotonin Re-uptake Inhibitors and the Serotonin Syndrome

Claudia L. Barthold and Jennifer A. Oakes

Serotonin re-uptake inhibitors (SRIs) are a diverse class of antidepressant agents that act by inhibiting re-uptake of serotonin (5-HT) at presynaptic receptors. Some of these drugs also have effects at norepinephrine receptors to varying degrees. These agents can be divided into two main categories: (1) selective serotonin re-uptake inhibitors (SSRIs) including fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram, and escitalopram, and (2) the serotonin–norepinephrine re-uptake inhibitors (SNRIs) including venlafaxine, desvenlafaxine, duloxetine, nefazodone, and milnacipran which is approved by the FDA for the treatment of fibromyalgia (but not depression) in the United States.

SRIs are widely prescribed as first-line therapy for depression and generalized anxiety disorder, obsessive–compulsive disorder, and neuropathic pain. The therapeutic effects of these antidepressant medications are mediated by blockade of the re-uptake of serotonin and/or norepinephrine into the presynaptic nerve terminal, allowing for buildup of these neurotransmitters in the synaptic cleft where they are active. Though these biochemical changes, and some behavioral changes, occur fairly rapidly, the full clinical therapeutic effects are delayed for up to 6 weeks (1).

In general, the SRIs have a wide therapeutic margin and safe side-effect profile. Because significant cardiac or neurologic toxicity is

rarely seen with overdose, these agents have replaced the more toxic, cyclic antidepressants (CAs) and monoamine oxidase inhibitors (MAOIs) (2). The most significant toxicity typically seen with SRIs is sedation and QTc prolongation. Seizures, antimuscarinic (anticholinergic) effects, and QRS prolongation are also reported in overdose with some of these agents. Fatalities are uncommon. A significant form of toxicity seen with this group is serotonin syndrome, which is a syndrome of serotonergic excess resulting from either drug interactions between two or more serotonergic agents or after overdose of SRIs or other serotonergic drugs. The SRIs are well absorbed from the gastrointestinal tract but may be delayed after an overdose, especially if coingested with agents that slow gut motility and absorption, such as anticholinergic agents or opioids. The SRIs are highly protein-bound and have large volumes of distribution, therefore not generally amenable to hemodialysis.

Half-lives range from 3 (paroxetine) to 144 (fluoxetine) hours and many agents have active metabolites and complex metabolism involving multiple hepatic microsomal enzymes. Activity at a variety of P450 sites contributes to drug–drug interactions seen with SRIs, and may increase the risk of developing serotonin syndrome. This risk is increased further when SRIs are used in combination with other drugs with serotonergic effects (e.g., MAOIs, dextromethorphan, or other SRIs).

Side effects of therapeutic use of SRIs are typically mild. These can include disruptions of sleep–wake cycles, sexual side effects, and weight gain. Symptoms such as mild agitation can occur with therapeutic use but are also an early sign of serotonin syndrome. A full history and physical examination can help differentiate between serotonergic toxicity and normal therapeutic side effects. There is a concern that the initiation of antidepressants can cause an increase in suicidal ideation or attempts especially in children and adolescents. This may affect the appropriate disposition or follow-up for a depressed patient newly started on SRIs.

There is no clear data on risks to the fetus after a single acute accidental or overdose exposure to an SRI in a pregnant woman. The severity of the mother’s symptoms, the fetus’ gestational age,

and any evidence of fetal distress should be considered in determining the need for evaluation or follow-up with the patient's obstetrician. In some cases, SRIs are prescribed therapeutically in pregnant women. Initiation of an SRI for a pregnant patient should be done in concert with her obstetrician and a mental health professional for concerns regarding fetal and neonatal effects of SRI exposure in utero.

CLINICAL PRESENTATION

Typically, signs and symptoms of toxicity occur in the first 6 hours especially for nonextended release preparations. Most SRIs are well tolerated in moderate overdoses presenting with little more than nausea or tremor, but more significant symptoms such as sedation, QTc prolongation, and seizures do occur (3). Patients can present with serotonin syndrome after overdose of an SRI. Citalopram and venlafaxine appear to be the most toxic of the SRIs with seizures and cardiac conduction abnormalities being more common than with other agents (3,4). Venlafaxine also been reported to cause widening of the QRS, similar to toxicity seen with TCAs (3).

In overdose, antimuscarinic (anticholinergic) effects can be seen with some agents. These may manifest as sedation, delirium, coma, hyperthermia, tachycardia, hypertension, dry mucous membranes, decreased bowel sounds, or urinary retention (see Chapter 344).

DIFFERENTIAL DIAGNOSIS

Because polydrug ingestions are the norm rather than the exception, especially in intentional adult overdoses, other agents with sedating or antimuscarinic properties must be considered as coingestants. Sympathomimetic agents (such as cocaine or amphetamines); dextromethorphan; anticholinergic agents such as diphenhydramine; hallucinogens such as lysergic acid diethylamide (LSD) or phencyclidine (PCP); alcohol; or withdrawal from benzodiazepines or alcohol can present with altered mental status, hallucinations, agitation, seizures, or autonomic instability. When evaluating a patient with hyperthermia and altered mental status, one should

always consider a possible infectious etiology such as meningitis, encephalitis, or septicemia as well as the possibility of neuroleptic malignant syndrome (NMS) which may also mimic serotonin syndrome but has a different etiology entirely. Neurotrauma, hypoxia, hyponatremia, and hypoglycemia should also be considered with altered mental status. Though cardiac conduction delays can be common in SRI intoxications, they can also be a sign of ischemic injury, so the patient's underlying cardiac status should be taken into account.

EMERGENCY DEPARTMENT EVALUATION

Since profound sedation can be seen in SRI intoxications, evaluation of a patient's ability to protect the airway is vital. Breathing and circulation should be immediately assessed. The patient should have cardiac monitoring with telemetry and serial electrocardiograph (ECG) evaluations. Blood chemistries should be obtained to look for acid–base and electrolyte abnormalities. Serum acetaminophen levels should be obtained on intentional overdose patients.

KEY TESTING

- There is no specific testing for SRIs
- EKG for conduction delay

ED MANAGEMENT

Excellent symptomatic and supportive care is essential. The emergency physician should protect the airway and assist breathing, with endotracheal intubation in the rare case of respiratory depression. Though hypotension is rare, blood pressure should be supported with fluids and vasopressor agents to maintain perfusion if needed. Glucose (with thiamine) and naloxone can be considered for patients with altered mental status. Flumazenil is not advised in suspected SRI overdoses or any suspected polydrug overdose. It may not reverse the sedation from the SRIs and may induce withdrawal seizures in a benzodiazepine-dependent patient (see Chapter 308). Additionally, as benzodiazepines are the first-line therapy for

seizures, flumazenil may impair the ability to control seizures should they occur from the overdose. Physostigmine to reverse the antimuscarinic side effects is probably best avoided because SRIs have some of the sodium channel blocking seen with the tricyclic antidepressants.

Seizures should be treated with benzodiazepines as first-line agents. If seizures persist and are not controlled by benzodiazepines consider barbiturates, propofol, and finally general anesthesia with electroencephalographic monitoring. Status epilepticus is not a typical feature of SRI-induced seizure activity, and its presence should prompt consideration of other causes such as trauma, infection, a secondary toxic exposure, or an unknown coingestant such as isoniazid.

If there is QRS prolongation ($>$100 msec or increasing on serial ECGs), serum alkalinization with sodium bicarbonate ($NaHCO_3$) should be considered. Initial dosing of one to three ampules (50 mEq each) IV, usually followed by continuous infusion of three ampules $NaHCO_3$ in 1 L of D_5W at a high maintenance infusion rate. The goal is normalization of the QRS or a maximum serum pH of 7.5 to 7.55. $NaHCO_3$ is the main treatment for TCA-induced QRS prolongation. The efficacy of this modality in QRS prolongation from other psychotropic agents including SRIs is variable, but it should be attempted if the patient has no contraindication to the sodium and volume load.

Drug-induced QTc prolongation from SRIs should be followed closely with serial ECGs, as the patient is at increased risk of torsades de pointes. QTc $>$470 msec on serial ECGs should be considered abnormal. Potassium, magnesium, and calcium levels should be normalized if possible, to mitigate their potential contribution to QTc prolongation.

Hyperthermia is a rare but potentially life-threatening result of SRI overdose or serotonin syndrome. Hyperthermic patients should be treated with active cooling and IV benzodiazepines if muscle hyperactivity and rigidity are contributing components.

Oral activated charcoal (1 g/kg) should be considered in any patient within 1 to 2 hours of acute overdose who is alert enough to protect the airway. Orogastric lavage is not indicated, as these agents have relatively low toxicity. Whole bowel irrigation (WBI) with polyethylene glycol solution should be considered for large acute ingestions of extended release preparations. The WBI solution should be given at 1 to 2 L/hr per nasogastric tube until the rectal effluent is clear. There is no role for hemodialysis, given the high level of protein binding and large volumes of distribution.

Beta-blockers or calcium channel blockers should generally be avoided in attempts to control drug-induced tachycardia or hypertension, unless there are signs of end-organ injury from these vital sign abnormalities. If necessary, it is best to use agents with a short duration of actions (e.g., nitroglycerin, nitroprusside, or esmolol), as they can be titrated down rapidly as appropriate.

CRITICAL INTERVENTIONS

- Establish IV access and cardiac monitoring with serial ECGs for QRS and QT prolongation.
- Benzodiazepines for agitation, muscle hypertonicity, hyperthermia, and seizures.
- Bicarbonate for QRS prolongation.

DISPOSITION

Admission to the hospital is indicated for the rare patient with persistent sedation, significant antimuscarinic effects, QRS or QT prolongation, seizures, or any clinical manifestations of serotonin syndrome. Persistently asymptomatic patients with no evidence of drug-induced conduction delays on their ECGs who have had an ingestion of a nonsustained release preparation can be observed and discharged 6 hours after ingestion. Psychiatric services should be considered for all intentional overdoses. Patients who have ingested large amounts of sustained release preparations may benefit from prolonged observation for possibly delayed toxic effects or serotonin syndrome.

SEROTONIN SYNDROME

Serotonin syndrome is the result of excess serotonergic stimulation in the CNS and remains the most common significant complication of SSRI overdose. Serotonin syndrome can occur with overdose of single SRI, when a second agent with serotonergic properties is added during therapeutic dosage of an SRI, and rarely after therapeutic initiation of a single SRI medication. The 5HT-2 A receptor has been implicated in most of the manifestations of serotonin syndrome, but it is likely that there is a significant contribution from other serotonergic receptors and possibly interactions with other neurotransmitters (5). As some of the SSRIs have prolonged elimination half-lives and pharmacologically active metabolites, serotonin syndrome can occur when a patient is switched from one SRI to another SRI or if multiple serotonergically active agents are combined. The emergency physician should be aware of this possibility and record a careful medication history that includes discontinued medications when evaluating someone for serotonin syndrome (Table 343.1).

TABLE 343.1
Common Drugs with the Potential to Produce Serotonin Syndrome (3,6)

Increased serotonin production
L-tryptophan
Increased presynaptic serotonin release
Amphetamines
MDMA (Ecstasy)
Cocaine
Decrease serotonin breakdown by MAO
MAOIs such as phenelzine, tranylcypromine, isocarboxazid, moclobemide, selegiline
St. John's Wort
Inhibition of serotonin reuptake
SRIs such as fluoxetine, citalopram, escitalopram, paroxetine, sertraline, fluvoxamine
Cyclic antidepressants
Clomipramine
Meperidine
Dextromethorphan
Tramadol

The syndrome is evident in up to 16% of patients who overdose on SSRIs (5). Clinical effects occur on a spectrum of mild to severe, and the history is vital in making the diagnosis and differentiating it from other etiologies, in particular NMS (Table 343.2).

TABLE 343.2
Comparison of Serotonin Syndrome and NMS

	Serotonin Syndrome	NMS
Cause	Serotonin excess	Dopamine blockade/ depletion
Onset of symptoms	≤24 hrs	Days to weeks
Neuromuscular effects	Hyperreflexia, clonus, hypertonicity (greater in lower extremities)	"Lead pipe" muscle rigidity in all muscle groups Bradyreflexia (tremor, hyperreflexia and clonus not as common)
Length of symptoms	Days	Days to weeks

Note: Varying degrees of altered mental status and autonomic instability are seen with both syndromes.

The signs and symptoms of serotonin syndrome can be divided into three major categories: (1) neuromuscular hyperactivity, (2) altered mental status, and (3) autonomic nervous system instability (Table 343.3). There may be abnormalities in only one or two of these categories. The most common clinical findings are myoclonus, hyperreflexia, confusion, hyperthermia, diaphoresis, and sinus tachycardia (1), but there is no single abnormality that is required for the diagnosis (7). Patients often have a combination of signs and symptoms, and these may not match one another in severity (e.g., a patient may have significant muscle hypertonicity with only mildly altered mental status and autonomic abnormalities). The diagnosis should thus be considered in patients with a history of recent exposure to serotonergic agents and findings in any of the major categories with some of the typical findings.

TABLE 343.3
Summary of Potential Clinical Findings Associated with Serotonin Syndrome (3,6)

Autonomic Instability	Altered Mental Status	Hyperactivity Neuromuscular
Tachycardia	Anxiety	Myoclonus
Fluctuating blood pressure	Confusion	Hyperreflexia
Diaphoresis	Drowsiness	Muscle rigidity
Flushed skin	Hallucinations	Tremor
Hyperthermia	Coma	Agitation
Tachypnea	Insomnia	Restlessness
Mydriasis	Dizziness	Ataxia
Unreactive pupils		Nystagmus
Diarrhea		Trismus
Abdominal pain		Opisthotonus
Excessive salivation		

The time of onset of symptoms after exposure to serotonergic agents is variable. Symptoms are often reported to develop within 1 to 2 hours of exposure (2). The syndrome has also been reported to occur several days after gradual increases in dosing of

antidepressant medications (5). There appears to be no relationship between the amount of drug ingested and the risk of serotonin syndrome, as it can occur with both therapeutic dosing and in overdose. Serum drug levels measured in patients with the serotonin syndrome have been either at therapeutic or below therapeutic levels in up to 90% of cases (1).

Mild neuromuscular effects can include tremor and akathisia that progress to increased reflexes and clonus and then to frank hypertonicity of muscles, which contributes to hyperthermia. Hypertonicity is often greater in the lower extremities. Mild confusion, agitation, and sedation can worsen to profoundly altered mental status, coma, and seizures. Autonomic instability ranges from minimally elevated heart rate, blood pressure, and temperature to frankly unstable vital signs with significant hypertension, tachycardia, and life-threatening hyperthermia ($>41^{\circ}C$).

Laboratory abnormalities may include evidence of rhabdomyolysis, with elevation of creatine phosphokinase, serum creatinine, and lactic acidosis from muscle tissue breakdown, seizures, or hyperthermia. Coagulation abnormalities (including disseminated intravascular coagulopathy), hypotension, and death have also been reported (7).

The differential diagnosis of serotonin syndrome includes sympathomimetic toxicity from agents such as cocaine, amphetamines (muscle hyperactivity, autonomic instability, potentially altered mental status), tetanus (opisthotonus, muscle spasms), strychnine poisoning (muscle spasms and rigidity), lithium toxicity (altered mental status, tremor, and clonus), and severe dystonic reaction infectious etiologies and metabolic derangements. The most similar condition, however, is the NMS. In contrast to patients with the serotonin syndrome, those with NMS have a history of recent commencement of, or increase in, dosage of neuroleptic medications; or a decrease or cessation in dopaminergic medications such as antiparkinsonian agents. Symptoms of NMS tend to develop (and later resolve) over days rather than hours; muscular hyperactivity is characterized by sustained “lead pipe”

rigidity rather than by myoclonus; and hyperreflexia is rarely, if ever, seen (see Chapter 338, Antipsychotic Agents).

Both the history and physical examination should focus on excluding other causes of the clinical picture. In patients presenting with a clinical picture suggestive of serotonin syndrome the history should focus on drug and medication usage. The vital signs should be repeated frequently, as autonomic instability can result in fluctuating blood pressure and pulse. Laboratory investigation should focus on excluding other causes of the clinical picture and evaluating for potential complications of the serotonin syndrome.

The treatment of serotonin syndrome is discontinuing all serotonergic agents along with aggressive symptomatic and supportive care. This includes active external cooling, airway management, and control of muscle tone with benzodiazepines. Agitation, myoclonus, hypertonia, or hyperpyrexia should be treated with intravenous benzodiazepines, crystalloids, and rapid external cooling measures. If no response is observed, paralysis and sedation will reduce muscle tone and decrease hyperthermia. All medications with serotonergic activity should be discontinued, and care should be used in choosing medications for treatment avoiding those with serotonin activity (e.g., ondansetron, fentanyl, valproate, metoclopramide) (5).

Various serotonin receptor antagonists have been used to treat serotonin syndrome, with inconsistent efficacy and unclear impact on outcome. Cyproheptadine is an oral antihistamine with antagonist effects at 5HT-1 A and 2 receptors that has shown some efficacy in case reports in mitigating symptoms (8). Initial control of symptoms can be attempted using 4 to 12 mg of cyproheptadine orally (or per nasogastric tube), followed by dosing of 2 mg every 2 hours until symptoms improve, followed by maintenance dosing of 8 mg every 6 hours (5,8). The maximum dose in a 24-hour period is 32 mg. It is most effective with mild to moderate toxicity typically within 1 to 2 hours of initial administration (8). Patients with more severe or progressive serotonin syndrome do not respond as well, if at all (8).

The antipsychotic chlorpromazine is a serotonin receptor antagonist that can be used for parenteral administration. It has been used successfully in doses of 50 to 100 mg IV and IM but should be preceded by adequate intravenous fluid hydration to prevent hypotension. Other side effects include sedation and dystonic reactions. The use of chlorpromazine in patients with NMS misdiagnosed as serotonin syndrome has the potential to worsen the former condition. Preliminary observations suggest that olanzapine antagonizes 5-HT-2-receptors and may be effective in reversing serotonergic toxicity (9). Further study is required to delineate its role in the treatment of serotonin syndrome.

Serotonin syndrome is usually self-limited and resolves in days after cessation of any serotonergic agent and aggressive symptomatic and supportive care.

CRITICAL INTERVENTIONS

- Aggressive active cooling for hyperthermia
- Aggressive benzodiazepine therapy and paralysis for neuromuscular stimulation

Any patient manifesting even mild signs and symptoms of serotonin syndrome should be admitted to the hospital for further care until symptoms resolve. Patients with significant autonomic instability are best managed in an intensive care setting.

SELECTIVE SEROTONIN RE-UPTAKE INHIBITOR DISCONTINUATION SYNDROME

After abrupt discontinuation of an SSRI, a mild and transient syndrome can occur. Typically starting in the first few days after discontinuation of an SSRI and lasting 1 to 2 weeks, symptoms can include headache, dizziness, nausea, irritability, insomnia, and paresthesias (10). Symptoms resolve spontaneously, but resolution is more rapid when the medication is restarted (10). Though abrupt cessation of SSRIs is to be avoided in the outpatient setting because of these symptoms, this should not be a concern for the emergency

physician in patients with an overdose. Resumption of treatment with an SSRI should be delayed until after any acute toxicity has resolved.

Common Pitfalls

- Prescribing medication with serotonergic effects (e.g., meperidine, tramadol, or dextromethorphan) in patients who are already taking serotonergic medications, especially MAOIs.
- Failing to admit patients with cardiac conduction delays (e.g., prolonged QTc) for telemetry.
- Failure to measure the temperature and begin cooling measures as indicated.
- Failure to recognize that a diagnosis of serotonin syndrome does not require all three elements of altered mental status, autonomic instability, and neuromuscular hyperactivity.

PART 9 • STIMULANTS AND HALLUCINOGENS

CHAPTER 344 Anticholinergic Agents

Fiona M. Garlich

Anticholinergic toxicity is a common side effect of many pharmaceutical agents, natural remedies, and plants in both the therapeutic and overdose settings. These agents are often abused recreationally for the desired effects of anticholinergic delirium and hallucinations. Anticholinergic symptoms result from inhibition of normal transmission of the neurotransmitter acetylcholine (ACh) in the peripheral and the central nervous system (CNS). ACh is released from cholinergic neurons and then acts upon two types of postsynaptic ACh receptors: nicotinic and muscarinic. Anticholinergic toxicity is more accurately referred to as antimuscarinic toxicity since it results from blockade of muscarinic ACh receptors, which are located in the brain and in organs innervated by parasympathetic nerve endings, such as the heart (via the vagus nerve), gastrointestinal (GI) tract, skin, lungs, bladder, salivary glands, lacrimal glands, and pupillary constrictor muscles.

Signs and symptoms of anticholinergic toxicity range from mild (e.g., dry mouth and blurred vision) to severe delirium with agitation, hallucinations, aggressive behavior, seizures, and vital sign abnormalities.

Numerous pharmaceuticals and toxins have anticholinergic activity (see Table 344.1). Muscarinic antagonists are commonly used therapeutically to treat parkinsonism, urinary incontinence, and motion sickness. Often overlooked exposures include ophthalmic mydriatic and cycloplegic drops such as scopolamine, and anticholinergic drops used to treat infantile colic (1). Anticholinergic toxicity may be seen with overdose and as an

iatrogenic complication of therapy with these medications, particularly in susceptible populations such as infants and the elderly (2). Agents such as tricyclic antidepressants (TCAs) and some antipsychotics have antimuscarinic activity in addition to their effects on norepinephrine, dopamine, and serotonin transmission. Anticholinergic symptoms can be a prominent part of the toxicity seen with overdose of these agents, contributing primarily to altered mental status and sinus tachycardia.

TABLE 344.1
Causes of Anticholinergic Toxicity

Anticholinergic Agents

Atropine

Scopolamine

Antiparkinsonian agents: benztropine, biperiden, procyclidine, trihexyphenidyl

Bladder antispasmodics: darifenacin, fesoterodine, oxybutynin, solifenacin, tolterodine, trospium

Tricyclic Antidepressants

Amitriptyline

Clomipramine

Desipramine

Doxepin

Imipramine

Nortriptyline

Antipsychotics

Phenothiazines: chlorpromazine, loxapine, mesoridazine, thioridazine

Atypical antipsychotics: clozapine, olanzapine, quetiapine

First-Generation H_1 Blockers

Chlorpheniramine

Cyproheptadine

Diphenhydramine

Dimenhyrdrinate

Doxylamine

Hydroxyzine

Meclizine

Pheniramine

Promethazine

Other Medications

Amantadine, cyclobenzaprine, carbamazepine

Disopyramide, orphenadrine, procainamide

Botanicals

Datura spp, especially *D. stramonium* (Jimson weed, thorn apple, "datura")

Brugmansia spp (angel's trumpet)

Atropa belladona (deadly nightshade)

Hyoscyamus niger (black henbane)

Mandragora officinarum (mandrake)

Chinese herbal medicines (including *Datura metel, Mandragora officinarum*)

The most commonly encountered pharmaceuticals with anticholinergic properties are the antihistamines, specifically the

"first-generation" H_1-receptor antagonists. These agents are competitive antagonists of histamine at H_1-receptor sites, but also have significant antimuscarinic activity. They are also more lipophilic and thus more sedating than the newer "second-generation" antihistamines. H_1-receptor blockers are widely available in both prescription and over-the-counter (OTC) formulations, and are used for the treatment of allergic conditions, as sleep aids, and as antiemetics. These agents are often combined with analgesics, sympathomimetics, caffeine, or anticholinergic compounds which can significantly alter the clinical presentation in overdose (3). Many OTC antihistamines are coformulated with acetaminophen, phenylephrine, or dextromethorphan. Abuse or overdose of these combination products can result in mixed symptomatology and concurrent poisoning by acetaminophen. Children and the elderly may develop anticholinergic toxicity or encephalopathy following exposure to topical antihistamines, especially if applied to broken skin (4).

First-generation antihistamines have other toxic effects in overdose, the most significant of which is sodium channel blockade. This can result in prolongation of the cardiac action potential, leading to widening of the QRS interval, as seen in TCA poisoning. Wide-complex tachycardia and cardiac arrest have been reported, especially with diphenhydramine and dimenhydrinate (4,5). The first-generation antihistamines astemizole and terfenadine were withdrawn from the US market due to prolongation of the QT interval and reports of torsade de pointes. Mild QTc prolongation has been reported with diphenhydramine (4).

Agents with anticholinergic side effects are often abused recreationally for their ability to produce sedation, hallucinations, or an altered mental state. Diphenhydramine is the most commonly abused medication in this group, but recreational use of benztropine, chlorpheniramine, dimenhydrinate, promethazine, and pheniramine is also reported. Abuse of OTC medications, especially sedating antihistamines and cough and cold preparations, has become increasingly popular among adolescents (6). Significant

toxicity can occur with recreational abuse and is complicated by the presence of coformulants.

Several plant species of the *Solanacea* family have potent anticholinergic properties and are used recreationally to induce hallucinations. The most common of these is *Datura stramonium,* or Jimson weed, which contains the tropane alkaloids atropine, scopolamine, and hyoscyamine. All parts of the plant are toxic, but the highest concentration of anticholinergic alkaloids are found in the seeds, which are harvested from locally grown plants or ordered online, and then eaten or brewed into teas. Recreational ingestion of *D. stramonium* can result in severe prolonged anticholinergic toxicity and death (7). Other plants with anticholinergic properties are listed in Table 344.1. See Chapter 355.

Another cause of anticholinergic toxicity is the adulteration of illicit drugs. Scopolamine is used as an adulterant in heroin and cocaine, leading to outbreaks of agitated anticholinergic delirium in drug users (8). Scopolamine can also be added surreptitiously to drinks, often in liquid form as so-called "knock-out drops," with the intent to facilitate sexual assault or robbery. See Chapter 309.

CLINICAL PRESENTATION

The patient presenting with anticholinergic toxicity may exhibit peripheral or central manifestations, or, more commonly, a combination of both (See Table 344.2). The classic anticholinergic toxidrome is characterized by mydriasis, dry skin and mucous membranes, flushing, fever, altered mentation, decreased bowel sounds, and tachycardia. These features provide the basis for the mnemonic "blind as a bat, dry as a bone, red as a beet, hot as a hare, mad as a hatter." Although this mnemonic describes the majority of anticholinergic symptoms, it ignores tachycardia, one of the most consistent and reliable clinical findings. However, in patients taking β-blockers or calcium channel blockers, infants, the elderly, and alcoholics with autonomic neuropathy, tachycardia may be absent. Hence, the absence of tachycardia does not rule out anticholinergic toxicity. Central anticholinergic effects range from

mild confusion and delirium to profound agitation, hallucinations, sedation, and coma. The severity and duration of central symptoms vary with lipid solubility, which affects the ability of an agent to penetrate the CNS. Pronounced, prolonged, and relatively isolated CNS effects have been described in patients exposed to lipophilic scopolamine and benztropine. At the extremes of age, and when anticholinergic agents are combined, delirium may persist for several days. Of note, the peripheral features of the toxidrome may be absent in patients who present to the hospital several hours following poisoning with an anticholinergic agent (2).

TABLE 344.2
Anticholinergic Symptoms and Signs

Peripheral Muscarinic Effects	Central Nervous Effects
Tachycardia	Fever
Mydriasis	Delirium
Loss of accommodation	Seizures
Dry skin and mucous membranes	Coma
Flushed skin	Agitation
Urinary retention	Psychotic behavior
Decreased bowel motility	Respiratory depression
Ileus	Cardiovascular collapse

While the majority of patients with pure anticholinergic toxicity demonstrate mild to moderate symptoms, severe complications and death have been reported (7). Significant morbidity can result from prolonged agitation, hyperthermia, acidosis, cardiovascular collapse, and the consequence of dangerous behavior due to impaired perception and judgment.

Patients with severe toxicity from overdose of H_1-receptor blockers can present with seizures, hypotension, rhabdomyolysis, hyperthermia, wide-complex tachycardia, and respiratory or cardiac arrest (4,5). It is likely that these complications result from the combination of anticholinergic effects with other pharmacologic properties of the agents involved. In adults with less severe

overdoses of first-generation antihistamines, CNS depression (drowsiness, ataxia, coma) is common due to central antihistamine effects. CNS excitation in children is more common as a result of their sensitivity to the anticholinergic effects (4). After antihistamine exposures, coma and seizures may occur within 30 minutes of ingestion. In children <2 years old, seizures have occurred with ingestion of 150-mg of diphenhydramine. Fatal diphenhydramine doses in adults may range from 20 to 40 mg/kg, but in infants as little as 12 mg/kg may result in death (4).

Overdose of TCAs often causes early anticholinergic signs such as sinus tachycardia and altered mental status, but toxicity following large ingestions is dominated by hypotension, seizures, and cardiac conduction delay resulting from other mechanisms (see Chapter 339).

DIFFERENTIAL DIAGNOSIS

Anticholinergic toxicity should be considered in any patient who presents with altered mental status, fever, urinary retention, tachycardia, or seizures. Anticholinergic symptoms may easily be misdiagnosed as a CNS infection, dehydration, heat illness, psychiatric disorder, or sepsis. Intoxications with salicylates, sympathetomimetics, hallucinogens, TCAs, antipsychotics, and drug withdrawal should also be considered in the differential diagnosis. The anticholinergic and sympathomimetic toxidromes can appear quite similar, but a patient with anticholinergic toxicity can be distinguished by the absence of diaphoresis and a diminished pupillary light reflex. Serotonin syndrome should also be considered, but should demonstrate neuromuscular findings that are typically absent in anticholinergic toxicity.

ED EVALUATION

A detailed history and complete physical examination are essential in the evaluation of anticholinergic toxicity or antihistamine poisoning. The physical examination should specifically search for anticholinergic features including pupil size, skin dryness, flushing,

bladder distention, and bowel sounds. Dry skin, which may not be overtly obvious on physical examination, can be assessed by placing a gloved hand in the patient's axilla. The absence of any moisture indicates pathologic dryness. Bladder distention can be assessed with a bedside ultrasound or placement of a foley catheter. Bowel sounds are typically absent or significantly diminished, though auscultation for bowel sounds is often impractical in the ED setting. Flushing of the skin may be present, but this occurs infrequently. A neurologic examination, including assessment of mental status, should be performed. Cardiac monitoring and an electrocardiogram (ECG) should be obtained to assess for prolongation of the QRS or QT intervals, particularly in the presence of tachycardia.

If seizures or altered mentation are present, further diagnostic testing such as computed tomography (CT) scan or lumbar puncture (LP), should be considered, especially if the history is unclear. Administration of physostigmine may obviate the need for further investigations if complete normalization of mental status occurs, confirming anticholinergic toxicity (9). In patients with significant symptoms, routine laboratory evaluation such as electrolytes, blood urea nitrogen, creatinine, glucose, and creatine kinase can direct supportive care. Checking serum concentrations of acetaminophen and salicylate can detect coingestion of these agents, especially from OTC products. Delayed absorption of acetaminophen may occur because of anticholinergic-induced slowed gastric emptying, making interpretation of the Rumack–Matthew nomogram difficult.

Toxicology screens are rarely useful. None of the medications or plants that cause anticholinergic toxicity are detected by standard immunoassay tests for drugs of abuse. Comprehensive testing with thin-layer and gas chromatography may assist in identifying an unknown or suspected xenobiotic, but delayed results rarely impact clinical management. As a result, the diagnosis must be made predominantly by the history and physical examination.

KEY TESTING

- Routine laboratory analysis including electrolytes, creatinine, and glucose
- Acetaminophen and salicylate concentrations with ingestion of OTC medication
- Consider head CT or LP for altered mentation or seizure

ED MANAGEMENT

The mainstay of therapy for poisoning with anticholinergic agents is supportive care, with the institution of advanced life support measures as necessary. Most patients with symptoms require a safe environment in which they cannot do themselves any harm. Comatose or hypoventilating patients should have appropriate airway intervention. Hypotension should be treated initially with intravenous (IV) crystalloid boluses followed by the use of pressor agents such as norepinephrine as needed. Agitation and seizures can be controlled with parenteral benzodiazepines. Occasionally large doses are required, resulting in impaired airway reflexes and necessitating endotracheal intubation.

GI decontamination with appropriate airway protection should be considered in patients presenting shortly after an ingestion of anticholinergic medications. A single dose of activated charcoal is adequate in most instances, but more aggressive interventions such as gastric lavage should be considered in patients with large ingestions of potentially toxic medications such as TCAs or diphenhydramine. An anticholinergic-induced delay in gastric emptying may result in the prolonged presence of pills in the stomach. There is no benefit for hemodialysis or multiple doses of activated charcoal to enhance elimination.

Physostigmine rapidly reverses central and peripheral signs of anticholinergic toxicity (9). It is a short-acting reversible inhibitor of the enzyme acetylcholinesterase, physostigmine allows ACh to accumulate in neuronal synapses and to overcome blockade of muscarinic ACh receptors. In pure, isolated anticholinergic poisoning, dramatic resolution of symptoms occurs within minutes of physostigmine administration, allowing the patient to verbally

confirm the history of poisoning with an anticholinergic agent, discuss coingestants, and deny symptoms consistent with alternative diagnoses (e.g., preceding fever, headache, and neck stiffness). This may prevent the need for escalating doses of benzodiazepines to control agitation, and obviate further diagnostic workup.

The use of physostigmine is not without risks and should be undertaken with caution. Case reports document asystole following physostigmine administration to critically ill patients with TCA overdose and wide QRS intervals (10; see Chapter 339). While controversial, physostigmine can be a safe and effective therapy when used in the appropriate clinical setting, that is, in a patient with a clear anticholinergic toxidrome, a supporting history of exposure, lack of coingestion of TCAs, and no ECG evidence of cardiac conduction delay (QRS prolongation or terminal r-wave in lead AVr). Other contraindications include bowel obstruction, significant cardiac or peripheral vascular disease, asthma, chronic obstructive pulmonary disease, and pre-existing urinary tract obstruction.

Physostigmine should be administered with continuous cardiac monitoring and atropine immediately available at the bedside. One to 2 mg is given slowly over at least 5 minutes (0.02 mg/kg in a child to a maximum of 0.5 mg). The onset of action is typically within minutes. If the response is incomplete, a repeat dose can be administered after 10 to 15 minutes. Clinical effects may last from 30 to 120 minutes, and dosing may be repeated as needed for recurrence of symptoms. If excessive cholinergic symptoms such as bradycardia, diaphoresis, bronchorrhea, or hypersalivation occur following physostigmine administration, atropine should be administered and titrated to effect (an atropine dose of half the administered dose of physostigmine is typically recommended).

When the diagnosis of anticholinergic toxicity is uncertain, or physostigmine administration is not safe or feasible, agitation may be controlled with parenteral benzodiazepines. Neuroleptic agents such as phenothiazines should be avoided because of their associated anticholinergic effects.

Wide-complex tachycardia associated with massive overdose of first-generation H_1-receptor antagonists (e.g., diphenhydramine) should be treated with a bolus of sodium bicarbonate to overcome sodium channel blockade, with consideration of serum alkalinization with sodium bicarbonate infusion (5). Class IA antiarrhythmics (e.g., procainamide) and class III agents (e.g., sotalol) should be avoided, as they can promote dysrhythmias as a result of prolongation of cardiac muscle cell repolarization.

CRITICAL INTERVENTIONS

- Rapidly control agitation with IV benzodiazepines to prevent rhabdomyolysis, hyperthermia, and injury to the patient or staff.
- Consider IV physostigmine to reverse agitation and coma after obtaining a normal ECG without cardiac conduction delay.
- Treat wide-complex tachycardia from first-generation H_1-receptor antagonist poisoning with IV sodium bicarbonate.

Patients with anticholinergic toxicity should be observed until they have normal vital signs, normal mental status, and all anticholinergic signs have resolved. This observation often requires admission to a monitored bed. Patients with agitation, coma, seizures, or cardiovascular instability should be admitted to an intensive care unit. The duration of anticholinergic delirium may be from 12 hours to several days depending on the agent and dose ingested. Patients with antihistamine poisoning who become or remain asymptomatic after a 4- to 6-hour observation period may be medically cleared. Suicide risk should be evaluated in patients with intentional overdoses.

Common Pitfalls

- Failure to consider the diagnosis of anticholinergic toxicity in patients with altered mental status (particularly agitated delirium), tachycardia, urinary retention, fever, or seizures.
- Failure to appreciate that anticholinergic symptoms may present as isolated central or peripheral manifestations.

- Use of physostigmine in patients with a history of TCA ingestion, with ECG evidence of cardiac conduction delay, or without adequate monitoring and resuscitation capability.
- Use of neuroleptics to treat anticholinergic agitation and hallucinations.
- Failure to obtain acetaminophen and salicylate serum concentrations in the patient who has ingested OTC medications.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Andis Graudins to this chapter in previous editions.

CHAPTER 345

Cocaine

Richard D. Shih and Judd E. Hollander

Cocaine (benzoylmethylecgonine) has been used for social, religious, and medicinal purposes for many centuries. Over the past several decades, its illicit use as a drug of abuse has risen dramatically. An estimated 40 million Americans have used cocaine at least once and for ages 12 and older, 4.2 million have used cocaine in the past year, and 1.4 million have used cocaine in the past month (1), making cocaine the most commonly involved drug of abuse for visits to emergency departments (EDs).

Cocaine is well absorbed on contact with mucous membranes or by pulmonary inhalation. It is derived from the *Erythroxylum coca* plant, which is found in abundance in Central America, South America, the West Indies, and Indonesia. In the manufacturing process, leaves are initially dissolved in hydrochloric acid to form the cocaine hydrochloride salt which is the form most often abused via nasal insufflation or IV injection. Crack cocaine or cocaine freebase are the alkaloid forms of cocaine that are produced by an extraction process utilizing a basic solution, a solvent (usually ether), and heat. The freebase form is close to 100% purity, whereas crack is approximately 75% pure. Crack and freebase are heat stable and thus can be smoked and absorbed by the lungs.

By the IV or inhalational routes, cocaine is rapidly distributed throughout the body with peak central nervous system (CNS) effects in 3 to 5 minutes. With nasal insufflation, absorption is slower and the effects peak at approximately 20 minutes. Although not a typical route of abuse, oral ingestion has even slower absorption with peak effects occurring at 40 to 60 minutes.

Cocaine has a half-life of 0.5 to 1.5 hours. It is predominantly metabolized by hydrolysis to the active metabolites ecgonine methyl ester and benzoylecgonine (BE). These two metabolites account for approximately 80% of cocaine metabolism and these metabolites have half-lives of 4 to 8 hours and many effects similar to their parent compound, cocaine. Other metabolites include cocaethylene, ecgonine, and norcocaine. Urine drug tests typically test for BE, which is usually present for 48 to 72 hours after use. Cocaine's effects typically last for several hours and may wear off while the urine test is still positive for urine cocaine metabolites.

Cocaine has a number of pharmacologic effects peripherally and in the CNS. It acts to augment the peripheral sympathetic system, producing tachycardia, hypertension, diaphoresis, arterial vasoconstriction, and dilated pupils. In addition, cocaine has local anesthetic effects. Because it is the only topical anesthetic agent in the amide group that has vasoconstrictive effects to control secretions and bleeding, it is often used for otolaryngology procedures and wound repair. The central effects of cocaine are very complex and not completely understood. It affects a number of neurotransmitters in the CNS; however, the net effect is augmentation of the sympathetic nervous system.

"Body packers" are individuals who have ingested containers of an illicit drug (most commonly cocaine and heroin). A packer, or "mule," is an individual who ingests a large number of carefully wrapped packages of highly pure drug as a means of concealing and smuggling it into the United States from a foreign country or into jail. These containers can be plastic bags, plastic vials, elastic wraps, elastic condoms, or other packaging material. In contrast, a "body stuffer" is someone who hastily ingests containers just before being arrested by police so as to conceal the evidence. The body stuffer typically has the drug in a plastic baggie or loose wrapping and is more likely to experience effects of cocaine.

CLINICAL PRESENTATION

The most commonly seen manifestations in the ED involve the cardiovascular (CV) and neurologic systems. Signs and symptoms of mild cocaine intoxication include normal or minimally increased blood pressure, pulse, respiratory rate, and temperature; agitation; anxiety; euphoria; headache; hyperreflexia; nausea; vomiting; mydriasis; pallor; diaphoresis; tremors; and twitching. Moderate intoxication may result in more severe hypertension, tachycardia, dyspnea, tachypnea, hyperthermia, confusion, hallucinations, marked hyperactivity, increased muscle tone and deep tendon reflexes, abdominal cramps, formication, and generalized but brief tonic–clonic seizures. Severe intoxication can result in hypotension, tachycardia (or preterminal bradycardia), ventricular dysrhythmias, Cheyne–Stokes respirations, apnea, cyanosis, severe hyperthermia, coma, flaccid paralysis, and status epilepticus.

Chest pain is a common chief complaint associated with cocaine use in EDs. Myocardial infarction (MI) associated with cocaine use is well established (2,3) and occurs in approximately 6% of patients presenting with this complaint (4). Cocaine causes coronary ischemia through coronary artery vasoconstriction, in situ thrombus formation, platelet activation, inhibition of endogenous fibrinolysis, and triggering an increase in the myocardial oxygen demand through generation of tachycardia and hypertension (2). Chronic users develop left ventricular hypertrophy, which can further exacerbate the oxygen supply–demand mismatch (2). It was previously thought that chronic cocaine use was associated with premature atherosclerosis but that has now been disproven (5). Other less common but equally important CV complications of cocaine use include atrial and ventricular dysrhythmias, both systolic and diastolic congestive heart failure, coronary and aortic dissection, dilated cardiomyopathy, and ischemia in other vascular beds (e.g., intestinal, renal).

Euphoria, the impetus for the recreational use of cocaine, is typically short-lived and without serious sequelae. The stimulatory effects of cocaine can lead to seizures. Cocaine-induced seizures are typically single and generalized with rare status epilepticus (6). Focal neurologic events such as hemorrhagic cerebral infarction and

subarachnoid hemorrhage are uncommon. Severe, persistent lethargy with an altered mental status can occur after prolonged and intense cocaine usage and has been termed the *cocaine wash-out syndrome.* This diagnosis should be made only after exclusion of the aforementioned neurologic catastrophes (i.e., after a normal computed tomography (CT) of the head and lumbar puncture, if indicated). The syndrome is thought to be from depletion of essential neurotransmitters following excessive cocaine usage and require 12 to 24 hours to resolve.

Rhabdomyolysis is another common manifestation of cocaine toxicity. Cocaine's stimulatory effects lead to severe agitation and marked muscular agitation and rigidity. Ischemia of the skeletal muscle beds may also contribute. Profound elevations in creatine kinase (CK) may be seen. Acute kidney injury is a result of muscle breakdown and renal tubular precipitation of the released muscle myoglobin. Concurrent development of severe hyperthermia and acute kidney injury can be life-threatening. Hyperthermia most commonly results from a combination of environmental exposure and heat production from excessive muscle activity from agitation and is often noted to be agitated delirium.

Cocaine has a number of direct and indirect effects on the lungs. Many of these effects are a result of the inhalation rather than direct toxin effects. Asthma exacerbations are frequently reported with crack cocaine, most likely a result of particulate byproducts of combustion. Crack use is typically associated with deep Valsalva maneuvers to maximize drug delivery, which can cause pneumothorax, pneumomediastinum, and noncardiogenic pulmonary edema. Other less common effects on the lung include pulmonary infarction, bronchiolitis obliterans, pulmonary artery hypertrophy, and alveolar hemorrhage. Treatment of these conditions follows standard management protocols, whether or not they are related to cocaine.

The intestinal vascular system is very sensitive to the effects of cocaine. Acute intestinal vascular infarction has been associated with all routes of administration. Although oral ingestion is not a common route of abuse, local intestinal and systemic effects can

occur when containers of cocaine leak or rupture in body stuffers and packers. Body packers are most often discovered by customs officers and present asymptomatically.

Habitual cocaine usage during pregnancy is associated with low birth weight, small head circumference, developmental problems, and a number of birth defects. Acute toxicity can also induce premature labor, eclampsia, and abruptio placentae. After delivery, neonates exposed to cocaine in utero are at risk for the development of neonatal withdrawal. This is a diagnosis of exclusion presenting with irritability, jitteriness, and poor eye contact.

DIFFERENTIAL DIAGNOSIS

Cocaine toxicity is associated with sympathomimetic effects which can be similarly seen with hypoglycemia, environmental and malignant hyperthermia, pheochromocytoma, manic psychiatric conditions, status epilepticus, and thyroid storm. Drugs with anticholinergic or sympathomimetic (i.e., amphetamines and bath salts) properties can present with a similar picture. Patients with persistent altered mental status need to be evaluated for possible meningitis and CNS lesions. Table 345.1 lists the differential diagnosis of chest pain related to cocaine use, which also includes reasons to be short of breath. New-onset seizures, epistaxis, hypertension, MI, intracranial hemorrhage, or psychiatric illness, especially in young patients, should suggest the possibility of cocaine use as well as other causes.

TABLE 345.1
The Differential Diagnosis of Cocaine-Associated Chest Pain

Aortic dissection	Pericarditis
Bacterial endocarditis	Pleurisy
Bronchospasm	Pneumonia
Esophageal illnesses	Pneumomediastinum
Gastrointestinal illnesses	Pneumothorax
Musculoskeletal injury	Pulmonary emboli
Myocardial infarction	Pulmonary infarction
Myocardial ischemia	
Myocarditis	

ED EVALUATION

The diagnostic evaluation of patients with cocaine toxicity relies on a history of cocaine use, recognition of signs and symptoms consistent with a sympathomimetic toxidrome, and evaluation of specific organ system complaints. The history should include the total amount and time of cocaine use in relation to symptom onset. Friends or witnesses of confused patients should be questioned about a history of seizures or syncope and antecedent activities. Many patients will deny cocaine use unless approached with reassurance and compassion or confronted with a positive urine test.

The physical examination should include complete vital signs and a detailed examination of the cardiac, pulmonary, and neurologic systems. Patients should initially have continuous cardiac monitoring.

When the history is clear and symptoms are mild, laboratory evaluation is unnecessary. In contrast, if the history is absent or unreliable or the patient manifests moderate or severe toxicity, laboratory evaluation may provide evidence of the severity or identify other causes. These include a complete blood count; determination of electrolyte, glucose, blood urea nitrogen, and creatinine levels; blood gas analysis; urinalysis; CK; and cardiac troponin. Qualitative toxicologic screening of blood and urine can confirm the diagnosis and rule out other intoxicants, but toxicology testing is indicated only when confirmation of drug use would change management, counseling, or referral patterns.

An electrocardiogram (ECG) should be obtained and a chest radiograph considered in patients with chest pain or moderate to severe toxicity. Those with prolonged, unexplained pain should have serial ECG and cardiac biomarker measurements to rule out MI. Many of the clinical parameters to assess ischemia or infarction are less reliable when compared to patients with traditional coronary artery disease. The ECG is less sensitive and specific for identifying ischemia or infarction in this setting, the CK is often elevated as a result of associated rhabdomyolysis, and false elevations in the MB fraction can occur. Cardiac troponin I testing identifies myocardial injury and MI (7). Observation for a 9- to 12-hour period can be used to evaluate patients with cocaine-associated chest pain. Patients without new ischemic changes on ECG, a normal troponin test, and no cardiovascular complications during this observation (dysrhythmias, acute MI, or recurrent symptoms) can safely be sent home with follow-up and a planned outpatient workup (8).

Persistent headache despite normalization of blood pressure is an indication for head CT scan and possible lumbar puncture to rule out intracranial hemorrhage. Patients with severe abdominal or back pain should be evaluated for intestinal or renal infarction and possible aortic dissection. The urine should be inspected and the serum CK level determined, to detect myoglobinuric renal failure.

Occult infections should be excluded in patients with fever, even though fever can be due solely to cocaine toxicity. A brief seizure clearly related temporally to cocaine use in an otherwise healthy person should be evaluated with CT to exclude serious underlying pathology, but does not require further workup, provided the patient is alert and coherent, has no headache, and has a normal neurologic examination. Patients suspected of body packing or stuffing should be evaluated by abdominal imaging and cavity searches (digital or visual examination of the rectum or vagina). Toxicity lasting for more than 4 hours suggests continued drug absorption and should prompt a similar workup.

The route of administration may influence the patient’s chief complaint or which organ system is affected. Intravenous users may present with fever and malaise secondary to infectious

complications such as cellulitis, endocarditis, hepatitis, pneumonia, and the acquired immunodeficiency syndrome. Chronic nasal use may lead to rhinitis, septal perforation, and epistaxis. Inhalational use may produce dyspnea, cough, or hemoptysis from reactive airway disease, “crack lung” pneumonitis, or pulmonary edema or may result in pulmonary barotrauma (e.g., pneumothorax, pneumomediastinum, pneumopericardium) from a Valsalva maneuver or from blowing smoke into the mouth of a partner. Patients with barotrauma may also complain of neck and chest pain with tachypnea, subcutaneous emphysema, or Hamman sign.

Behavioral disorders (e.g., agitation, combative behavior), headache, back pain (renal infarction or aortic dissection), abdominal pain (mesenteric ischemia), altered level of consciousness, or cardiopulmonary arrest are other presentations that may follow the use of cocaine by any route. Patients with excited delirium, severe agitation, an elevated temperature, and metabolic acidosis deserve immediate attention. Patients may present as victims of trauma because of the violent, irrational, and risk-taking behavior associated with drug use. Delayed CV complications can sometimes occur and MI has been reported in the first few days after cocaine use but has also been reported 1 to 2 weeks after last use.

Manifestations of chronic cocaine abuse include anorexia, insomnia, formication, depression, impotence, weight loss, paranoia, and psychosis. Halo vision (lights around objects) and “snow lights” (flashes in the peripheral fields) have also been described.

KEY TESTING

- Mild Toxicity
  None necessary
- Moderate to Severe Toxicity
  CBC, electrolytes, glucose, BUN, UA
  CK for rhabdomyolysis
  CXR for persistent SOB and chest pain
  ECG and troponin for suspected ischemia

CT (head/chest/abdomen) for persistent complaint

ED MANAGEMENT

Management depends on the specific complaint and presentation. Patients presenting with a sympathomimetic toxidrome are at risk for hyperthermia and rhabdomyolysis. After initial attention to the airway and CV status, management should focus on lowering any elevated core body temperature, halting further muscle agitation and heat production, and giving IV fluids to ensure a good urinary output. The agents of choice for muscle relaxation in this setting are benzodiazepines and in severely agitated individuals, control should be obtained with rapid use and use of supranormal cumulative doses may be necessary.

Patients with severe hypertension or tachycardia needing pharmacologic measures can usually be safely treated with benzodiazepines. When large doses of benzodiazepines are not effective, intravenous nitroprusside or phentolamine should be considered (4). β-Antagonists or compounds with partial β-blocking effects are contraindicated as the use of β-antagonists in the setting of cocaine intoxication can lead to unopposed α-stimulation, with resultant marked increases in hypertension and worsening coronary vasoconstriction (2,4).

Patients with suspected cocaine-induced ischemia or MI should be treated similarly to those with traditional acute coronary syndromes (ACSs), with some notable exceptions (2,4). Aspirin, nitroglycerin, and heparin remain important initial therapies. Intravenous benzodiazepines should be provided as early management (2,4,9). They will decrease the central stimulatory effects of cocaine, thereby indirectly reducing the CV toxicity of cocaine (2,4). β-Antagonists are contraindicated, as they exacerbate cocaine-induced coronary artery vasoconstriction (2,4). Percutaneous interventions (angioplasty) are preferred over fibrinolysis, which has no proven efficacy in the setting of cocaine-associated MI and a possible reduced safety profile. There is an increased likelihood of interventions being performed in patients who are not sustaining an

acute infarction because young patients have a high prevalence of early repolarization and “false-positive” ST-segment elevations on the ECG. Such a therapy should, therefore, be used with caution. Finally, there are anecdotal reports of the safety and efficacy of phentolamine, an α-antagonist, for treatment of cocaine-associated ACS (2,4). Verapamil reverses cocaine-induced vasoconstriction, but several animal experiments suggest that it exacerbates CNS toxicity. Thus, it may have a role in patients with continued ischemia who do not have signs of central stimulation from cocaine.

Supraventricular dysrhythmias due to cocaine toxicity may be difficult to treat. Adenosine can be administered, but its effects may be only temporary. Use of calcium channel blockers in association with benzodiazepines appear to be most beneficial. β-Blockers should be avoided (2,4).

Ventricular dysrhythmias may be a result of excess adrenergic tone or cocaine’s sodium channel blocking effects. Management with benzodiazepines, lidocaine, and/or sodium bicarbonate appears to be most useful (2,4). Bicarbonate is preferred when patients have dysrhythmias directly after the use of cocaine. In this setting, the dysrhythmias are presumably related to the type I antiarrhythmic effects of cocaine. Bicarbonate reverses cocaine-associated QRS widening. Lidocaine can be used when dysrhythmias appear to be related to cocaine-induced ischemia (10). ECG evidence for the type I antiarrhythmic effects of cocaine has often disappeared by the time symptomatic ischemia develops. There is no data regarding the use of amiodarone.

Cocaine-induced seizures are typically brief and self-limited. For refractory cases, benzodiazepines and phenobarbital are the first- and second-line agents, respectively. Phenytoin is not recommended.

Patients with suspected cerebrovascular infarctions and hemorrhage should be treated the same as other patients with these conditions. Intracranial and systemic hypertension necessitating treatment is accomplished using standard therapies, except that β-blockers should not be utilized.

The main objective with asymptomatic body packers is to eliminate the packages out of the gastrointestinal system. Whole-bowel irrigation with subsequent radiologic verification of passage of all drug-filled containers may be warranted.

Body stuffers who show clinical signs of toxicity should be treated similar to other cocaine-exposed individuals. In addition, activated charcoal should be administered liberally.

Symptomatic body packers should be treated aggressively, because rapid deterioration and severe toxicity can result from leakage from a single package causing potentially massive exposures. Immediate surgical removal of the ruptured package(s) may be lifesaving. Aggressive supportive care with activated charcoal and benzodiazepines is warranted as preparations are made for surgery.

CRITICAL INTERVENTIONS

- Rapidly cool and sedate the hyperthermic and agitated patient.
- Assess patients with cocaine toxicity for myocardial ischemia/MI, dysrhythmias, hyperthermia, and rhabdomyolysis.
- Administer intravenous benzodiazepines for CNS and cardiovascular toxicity.

DISPOSITION

Patients with severe agitation, hyperthermia, and possible rhabdomyolysis need to be admitted. Patients with cocaine-associated chest pain need to be assessed for risk of CV events. Criteria for patients with a low risk of CV events that are safe for ED discharge after a brief observation period include lack of ischemic changes on ECG; normal serial cardiac troponin I values; and no dysrhythmias, or recurrent symptoms during a 9- to 12-hour observation period (8). Most patients with ED cocaine-associated chest pain (~70%) will meet these criteria (8). Coronary computerized tomographic imaging of the coronary arteries can be used to identify low-risk individuals and shorten the duration of observation (11).

The disposition of patients with neurologic complications is the same as for other patients with these conditions. The likelihood of compliance with outpatient follow-up should be considered when contemplating the discharge of patients who may need further evaluation. If definitive care cannot be provided at the site of presentation, transfer may be necessary. Personnel with advanced life-support training should accompany patients requiring transfer. Substance abuse counseling and treatment should be discussed with all patients with referral if possible.

Body stuffers who remain asymptomatic for 4 to 6 hours may be discharged after treatment with activated charcoal. Body packers need to be admitted until packets have been removed.

Common Pitfalls

- Failure to aggressively treat patients with agitated delirium from cocaine.
- Failure to consider cocaine toxicity in the differential diagnosis of patients with chest pain, seizures, agitation, altered mental status, and dysrhythmias.
- Failure to recognize the limitations of the ECG in the evaluation of cocaine-related chest pain.
- Failure to appreciate the differences between the management of cocaine-related chest pain and traditional therapy for ACS.
- Failure to recognize the dangers of using β-adrenergic antagonists to treat cocaine toxicity.
- Failure to ensure the rectal passage of cocaine-filled packages in body packers prior to discharge.

CHAPTER 346

Hallucinogens

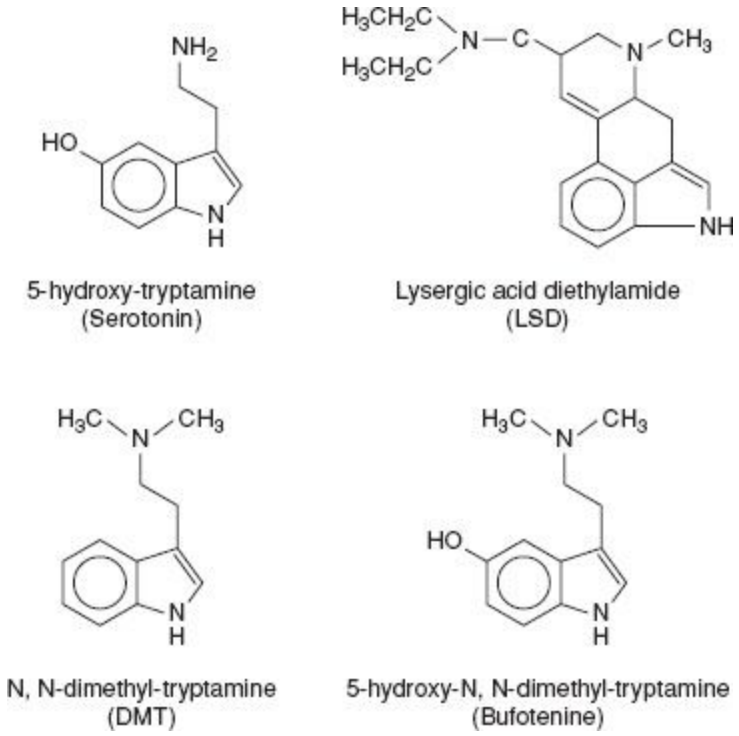
Howard A. Greller

Hallucinogens, from the Latin *alucinari* (to "wander in mind"), are a diverse class of xenobiotics that primarily alter sensory perception and interpretation, without altering orientation. The term *hallucinogen* is the medicolegal descriptor for this group of related compounds, whereas *psychedelic* is a common layperson descriptor. *Hallucination* is the perception of phenomena or objects that have no basis in reality (e.g., pink elephants). Visual hallucinations tend to have toxic metabolic causes, whereas auditory hallucinations tend to be primarily psychiatric or organic. The term hallucination contrasts with *illusion,* in which there is misinterpretation of a sensory perception (e.g., a coat hanging in a dark room is perceived as being a person). A *synesthesia* is a mixed perception (e.g., hearing color or seeing taste). *Psychotomimetic* describes a substance that causes psychological and behavioral changes resembling psychosis. An *entactogen* is a substance that enhances feelings of empathy, love, and emotional closeness and facilitates expression of emotions (e.g., methylene-dioxy-methamphetamine [MDMA]—ecstasy), whereas an *entheogen* ("generating the divine within") is a psychoactive xenobiotic used in a ritualistic religious or spiritual context (e.g., 3,4,5-trimethoxyphenylethylamine—mescaline) (1).

Plant and animal species have been used in religious, spiritual, and other practices for centuries. The Rig-Veda, an Indian text more than 3,000 years old, praises soma, believed today to be the mushroom *Amanita muscaria,* containing the psychoactive compound muscimol (2,3). The modern era of hallucinogens had its origins with Albert Hofmann, who synthesized lysergic acid

diethylamide-25 (LSD) in 1938. LSD was subsequently used as a therapeutic adjunct for psychotherapy but found its way into recreational use in the 1960s. As a result of concerns about birth defects and other toxicity, federal law in the mid-1960s banned LSD. Many hallucinogens are Food and Drug Administration (FDA) schedule I agents (4). In adolescents (age 12 to 17), overall hallucinogen use has declined in the 10-year period between 2002 and 2012 whereas the 18- to 25-year-old group had the highest prevalence of use within the last year. There has been a recent increase in the use of other hallucinogenic compounds, such as "foxy" (5-methoxy-*N, N*-diisopropyltryptamine), DMT (*N, N*-dimethyltryptamine), psilocybe mushrooms, phencyclidine (PCP), and ketamine (5).

The mechanism of hallucinogenesis has not been completely elucidated. Although derived from widely different sources and often chemically distinct, most hallucinogens share a structural similarity to serotonin (eFig. 346.1), and can be classified by structure. The tryptamine derivatives share the pyrrole structure of the indole ring. The amphetamine derivatives typically considered "hallucinogenic," such as MDMA, share the methoxylated or methylenedioxylated catechol ring. Each of these structural features appears to be essential to hallucinogenic activity (1,3,6). The similarity of LSD and other hallucinogenic compounds to serotonin provides them with agonist activity at the 5-HT_2 receptor. Specifically, the 5-HT_{2A}-receptor subtype found predominantly on a population of postsynaptic neurons in the cerebral cortex has been implicated by functional studies in the modulation of hallucinations (7). Additional mechanisms for the generation of hallucinations include activity at the κ-opioid receptor, as is the case with *Salvia divinorum* and ibogaine (8), which are structurally unrelated to serotonin.



eFIGURE 346.1 Hallucinogenic compounds and their structural similarity to serotonin.

LSD is a semisynthetic lysergamide compound derived from the ergot fungus *Claviceps purpurea.* There are other naturally occurring analogs of LSD found in the seeds from plants of the morning glory family (*Convolvulaceae*), including the South American morning glory, the Mexican morning glory, and Hawaiian woodrose (2,9). LSD is very potent, with hallucinogenic doses in the range of a few hundred micrograms. It is most commonly administered through the oral route, generally as a fancifully designed blotter paper. The perforated paper defines a dosing unit, and the designs provide "branding." Other forms include impregnated gelatin ("window panes") or microdots (small pills or tablets), and occasionally as a liquid (4).

Mescaline, or 3,4,5-trimethoxyphenylethylamine, is a phenylethylamine compound that is derived from the peyote cactus (*Lophophora williamsii*). Although mescaline can be isolated from the cactus, this is a difficult process, and most of the time the compound is ingested in its natural form. Typically, a few of the small cactus

crowns or “buttons” are removed, dried, and then ingested (4). The phenylethylamine analogs of mescaline are also used in an attempt to produce similar hallucinosis. Although the primary clinical effects of recreational doses of ecstasy (MDMA; see Chapter 348) do not involve hallucinations, hallucinations may occur at very high doses. The seeds of nutmeg (*Myristica fragrans*) are known to contain myristicin and elemicin, two mescaline-like substituted amphetamines with hallucinogenic properties (2,9). Up to 20 g of the ground spice need to be ingested to produce the hallucinatory effects, at the expense of significant gastrointestinal (GI) distress. Other phenylethylamine compounds include the “2 C” compounds including 2 C-B (4-bromo-2, 5-dimethoxyphenethylamine) and 2 C-T-7 (2, 5-dimethoxy-4-N-propylthiophenethylamine.)

The tryptamines are a group of structurally related compounds that produce hallucinosis. Psilocybin (4-phosphoryloxy-*N, N*-dimethyltryptamine) and psilocin (4-hydroxy-*N, N*-dimethyl-tryptamine) are two compounds of the indolalkylamine class isolated from mushrooms of the *Psilocybe* genus (1,2,9). The two most common species are the “liberty cap” (*Psilocybe semilanceata*) and *Psilocybe cubensis*. The spores of these mushrooms are not considered a controlled substance (although the mature mushrooms are), are readily available through a variety of sources, and are easy to grow into mature mushrooms. Being a natural product, the amount and type of hallucinogenic compound contained within any singular mushroom vary widely, and therefore there is no “typical” dose (see Chapter 354).

“Foxy” or “foxy methoxy” (5-methoxy-*N, N*-diisopropyltryptamine, 5-MeO-DIPT) and α-methyltryptamine (AMT) are tryptamine derivatives (1,4,5). Both drugs are available as capsules filled with powder and are orally bioavailable. DMT (*N, N*-dimethyl-tryptamine) is a tryptamine derivative of the Yakee plant (*Virola calophylla*). Ayahuasca is a psychotropic plant that is used as a tea throughout the Amazon basin in traditional medicine and shamanistic practices. Ayahuasca is made by steeping the pounded stems of the vine *Banisteriopsis caapi* alone or in combination with the leaves of *Psychotria viridis*. This combination is

ethnopharmacologically interesting because *P. viridis* contains DMT and *B. caapi* contains alkaloids such as harmine and tetrahydroharmine. DMT is normally metabolized by GI monoamine oxidase (MAO), and harmine and the other β-carboline alkaloids are MAO inhibitors (1,2,9). Thus the combination of the two plants allows for the increased bioavailability of the DMT.

Secretions of the modified parotid gland of the Colorado River toad, *Bufo alvarius,* contain a mixture of "defensive" chemicals designed to protect from predators. These chemicals include catecholamines, cardioactive steroids, and *bufotenine* (5-methoxy-*N,N*-dimethyltryptamine, 5-MeO-DMT), a potent hallucinogenic compound. People engage in the practice of "toad-licking" in attempts to experience the psychedelic properties of this chemical. This practice is often complicated with the consequences of the other compounds contained within the secretions, most notably cardioactive digoxin-like steroids (see Chapter 325) (1).

S. divinorum, a member of the mint family, has been used for centuries by the Mazatec Indians of Oaxaca, Mexico. The active compound is a neoclerodane diterpene, salvinorin A, structurally unrelated to any of the previously described hallucinogenic compounds and believed to exert its clinical effects through action at the κ-opioid receptor. *S. divinorum* is taken orally, with rapid oral–mucosal absorption, and by smoking (5,8).

Ibogaine is derived from the root of the *Tabernanthe iboga* plant, found primarily in West African nations. Ibogaine has gained recent attention as a potential treatment for addiction to compounds such as cocaine and heroin and is being investigated by the FDA for such purposes. Ibogaine is taken orally (2,4,5,9).

CLINICAL PRESENTATION

Unlike most other drugs of abuse, users of hallucinogens rarely present acutely to the healthcare provider (4,5). Hallucinogens in general have few significantly dangerous adverse side effects, and patients generally present to the emergency department (ED) for secondary reasons (e.g., trauma) or for "bad trips." The unique

nature of hallucinogens defines their clinical presentation. Unless combined with other drugs, patients should be alert and fully oriented and able to give a history of use. A clear sensorium is a key historical and examination point, suggesting the use of LSD. This contrasts with drug-induced delirium, such as that associated with PCP, in which, by definition, the patient's orientation is altered. In addition, in an attempt to obtain a hallucinogen, patients are commonly exposed to more sympathomimetic compounds (such as 25I-NBOMe) and have more physiologic derangements.

Hallucinations or illusions are alterations in the perception of time and body image and changes in the interpretation of sensory information. Hallucinogenic experiences are commonly referred to as a "trip," and the experience tends to be an extremely personal one. The perceptual changes that users perceive can affect any of the senses: hearing, taste, smell, touch, or sight. The person can experience exaggeration, diminution, or mixing (synesthesias) of their sensory perception. The users' sense of time may be altered, generally slowed, as may their sense of space. Body dysmorphisms are common, in which personal physical features take on abnormal proportions. Events can be perceived as hyperreligious or evil. Additional clues to the diagnosis include the sympathomimetic effects of some of the compounds involved, although these effects are usually mild and rarely dangerous. Common physical signs and symptoms of acute intoxication include mydriasis, diaphoresis, piloerection, tremors, and mildly elevated blood pressure, pulse, respiratory rate, and temperature. These findings may be masked by the coingestion of ethanol or other sedative–hypnotic agents.

Injury is the predominant adverse event related to hallucinogen use, as a result of the acute behavioral effect of the drug. There are few, if any, dangerous physiologic effects of the drugs themselves. The psychological effects can be overwhelming, and occasionally the hallucinations can be perceived as frightening or threatening ("bad trips") causing the patient to panic or respond in a manner causing injury. These experiences can include or engender paranoia, acute psychosis, panic, and significant depression. Suicide and unintentional death have been reported (2,5). There is no

withdrawal syndrome from hallucinogens, although tolerance and crosstolerance between compounds can occur.

Mescaline use is associated with significant, unpleasant side effects. Initial signs and symptoms include nausea, vomiting, abdominal pain, diaphoresis, nystagmus, and ataxia. These symptoms typically resolve within 1 to 2 hours of ingestion and precede the onset of the hallucinations, which begin within 4 to 6 hours and typically last for 6 to 12 hours (5).

Hallucinogenic doses of nutmeg cause severe side effects, such as dizziness, flushing, tachycardia, nausea, vomiting, constipation, and panic. Because of the relative severity of the side effects, it is not a popular means of producing hallucinations. When ingested, the hallucinations begin within 1 to 4 hours and last 12 to 24 hours. Many users report an extended period of sleep after use (upward of 16 hours).

Ingestion of psilocybe mushrooms is typically associated with nausea and sometimes vomiting. Onset of effect is approximately 30 minutes, and the duration is typically 4 to 6 hours. The effects are described as being typically “less intense” and more illusionary than those produced by LSD (1,2,9). AMT has a longer duration of effect (approximately 12 to 24 hours) than that of Foxy (between 3 and 6 hours). Toad licking has resulted in digoxin-like bradycardia and significant adverse effects from other components of toad secretions (1).

The hallucinogen persisting-perception disorder (HPPD), commonly known as “flashbacks,” associated with the use of LSD should not be confused with prolonged sensory perception (afterimages), also known as palinopsia. Patients with HPPD characteristically experience, in the absence of the drug, recurrent perceptual disturbances similar to those encountered during acute intoxication. HPPD is often triggered by stress, illness, or other challenges. HPPD can occur after a single use of the drug and may last for a prolonged period (up to years) (1,10). HPPD is associated with the use of phenothiazine antipsychotics to control the acute behavioral symptoms of acute intoxication, suggesting that sedatives such as benzodiazepines, rather than antipsychotics, should be used

for this purpose. Proposed therapies for HPPD include clonazepam, carbidopa, and psychotherapy. A rare reported adverse effect of LSD is permanent psychosis (10).

The time of onset and duration of effect can help determine the identity of the hallucinogen (see Table 346.1). Long-acting agents include LSD, mescaline, and nutmeg. Medium-acting agents include psilocybin, psilocin, Foxy, AMT, and *Bufo* sp–toad toxins. Short-acting hallucinogens include DMT, ibogaine, and salvinorin A.

TABLE 346.1
Common Hallucinogenic Compounds

Common Name	Name	Onset (hrs)	Duration (hrs)
DMT	*N,N*-dimethyl-trypt-amine	Rapid	0.5 to 1
Salvia divinorum	Salvinorin A	Rapid	1 to 2
Foxy	5-methoxy-*N,N*-diiso-propyltryptamine	Rapid	3 to 6
Psilocybin	4-phosphoryloxy-*N,N*-dimethyltrypt-amine	0.5	4 to 6
LSD	Lysergic acid diethyl-amide	1 to 4	4 to 12
Mescaline	3,4,5-trimethoxyphenyl-ethylamine	4 to 6	6 to 12
Nutmeg	5-allyl-1,2,3-trime-thoxybenzene	1 to 4	12 to 24
AMT	α-Methyltryptamine	Rapid	12 to 24
Ibogaine	Ibogaine	4 to 8; 10 to 20	12 to 24

Smoking DMT leads to effects that typically begin within minutes and last between 30 and 60 minutes. Rapid onset and short duration of action has earned DMT the moniker “the businessman’s lunch,” because the user can experience a “trip” in the time allotted for a meal (1,4,5). Following the ingestion of ayahuasca, DMT also has a rapid onset of action and short duration of effect (1,2,9).

The ingestion of *S. divinorum* produces effects that begin in 5 to 10 minutes and last approximately 1 to 2 hours. When the vapor is

inhaled or the plant is smoked, effects begin in seconds and last about 30 minutes (5,8). Ibogaine ingestion can cause both early (4 to 8 hours after ingestion) and late (10 to 20 hours after ingestion) hallucinations (2,4,5,8).

DIFFERENTIAL DIAGNOSIS

Other abused agents that can cause hallucinations include sympathomimetics, anticholinergics, and dissociative anesthetic agents and related compounds. Cocaine and amphetamines are associated with psychosis at high doses or following binges and those atients characteristically develop a delusional state that does not always involve clear hallucinations. Symptoms may last for several days but typically respond to antipsychotic medications. Anticholinergic agents (e.g., scopolamine and atropine) may produce dramatic epidemic hallucinations when teenagers discover Jimsonweed (*Datura stramonium*) and ingest the seeds. Patients generally have other manifestations of the anticholinergic syndrome and are almost always delirious. Dissociative anesthetic agents, such as PCP, ketamine, and the related compound dextromethorphan, produce hallucinations that are generally described as dysphoric which can cause wild and unreasoned behavior. Clinical features include delirium and prominent nystagmus. Autonomic manifestations are usually more prominent than hallucinations in each of these conditions. In contrast, with traditional hallucinogens such as LSD, hallucinations are prominent, and autonomic effects are usually mild.

Hallucinations have been reported as idiosyncratic reactions to almost all medications. Street-drug adulterants (e.g., cyanide, local anesthetics, quinine, quinidine, caffeine, theophylline, and strychnine) should be considered in the differential of hallucinosis. Because central nervous system (CNS) structural, infectious, and psychiatric conditions can cause hallucinations, exposure to a hallucinogenic agent should be a diagnosis of exclusion. With or without the history of hallucinogen exposure, these conditions should always be considered in the differential diagnosis.

ED EVALUATION

The history from family, friends, or the patient, who is usually cooperative and oriented, should include the name or description of the hallucinogen, the time of ingestion, amount(s) taken, the route of exposure, and the nature and time of onset of hallucinations and other symptoms. Slang names may provide a presumptive identity, if the chemical name is not known. A history of previous drug use, psychiatric problems, and medical conditions, particularly cardiovascular disease, should be documented. The clinician should specifically explore the possibility of concomitant traumatic injuries.

The physical examination should focus on the mental status, neurologic evaluation, and cardiovascular system. Vital signs documented and repeated frequently. The patient should be examined carefully for evidence of trauma, underlying disease, and heat-related illness.

Ancillary testing is neither necessary nor useful in patients with mild hallucinogen intoxication, except to rule out other diagnoses. Patients with moderate or severe symptoms (e.g., excessive agitation and significantly abnormal vital signs) should have a chest radiograph; cardiac monitoring and a 12-lead electrocardiogram (ECG); complete blood count; determination of electrolyte, glucose, blood urea nitrogen, creatinine, and creatine kinase levels; and urinalysis performed to exclude other conditions or exposures. Significant psychomotor agitation can occur with a variety of perceived stimuli, and rhabdomyolysis should be considered. Routine toxicology screens are rarely sensitive or specific enough to provide confirmation or exclusion of another agent as the causative etiology of a specific clinical presentation. Quantitative blood (or urine) hallucinogen levels are not clinically useful or routinely available.

KEY TESTING

- Rapid glucose measurement and core temperature are useful in all patients

- ECG and other tests as needed for supportive care or to exclude other causes
- Radiographs to evaluate suspected trauma

ED MANAGEMENT

Management is supportive. Standard life-support measures should be instituted as needed, but an intravenous line is often not needed. The focus of care should then be to provide a calm, quiet environment for the patient. Providers should attempt to reduce the patient's anxiety, help to provide a foundation for reality testing, and provide continued, empathetic reassurance. In cases in which the experience is causing the patient significant agitation or distress, pharmacologic sedation with a benzodiazepine should be provided. Phenothiazines should be avoided because they have been implicated in HPPD (10). Although activated charcoal can bind most, if not all, of these compounds, the efficacy of this intervention is undefined. Because consequential morbidity is exceedingly rare and because GI decontamination may be particularly unpleasant for a patient who is hallucinating, its use is unnecessary except for patients with significant coingestions.

CRITICAL INTERVENTIONS

- Provide a calm, quiet environment with continuous observation and repeated reassurance.
- Administer benzodiazepines for persistent or severe agitation or psychological distress.

DISPOSITION

For the majority of patients presenting after use of a hallucinogen, their disposition will be discharged. In the absence of any adverse sequelae (e.g., trauma, rhabdomyolysis, electrolyte abnormality, etc.), the patient should be watched until reality testing is assured, and appropriate referral to a psychiatrist or substance abuse program can be provided. Admission is warranted only for

persistence of psychosis or if the patient has a concomitant medical or surgical issue that makes this necessary.

ACKNOWLEDGMENTS

The author gratefully acknowledges the contributions of Lewis S. Nelson and Christopher H. Linden to previous editions of this chapter.

Common Pitfalls

- Failure to obtain a complete set of vital signs, especially an accurate core temperature.
- Failure to differentiate between hallucinations and delirium; patients with drug-induced hallucinations have clear orientation with altered content.
- Failure to make safety of the patient and staff a priority.
- Failure to consider metabolic, structural, infectious, traumatic, and psychiatric etiologies of the hallucinatory state.
- Failure to screen for occult conditions caused by the behavioral abnormalities of these compounds, such as rhabdomyolysis.
- Failure to consider coingestants or nonclassical hallucinogen-producing compounds (i.e., anticholinergic agents) and their specific toxicities.

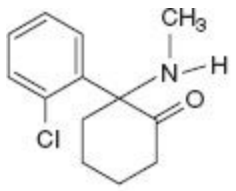
CHAPTER 347 Phencyclidine and Ketamine

Cyrus Rangan

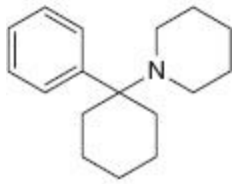
Phencyclidine [PCP, 1-(1-phenylcyclohexyl)-piperidine], first synthesized in 1926, is a powerful analgesic and amnestic with minimal respiratory depression. It was used as a general anesthetic (Sernyl) in the 1950s but use in humans ceased in 1965 because of emergence reactions; veterinary use ceased in 1979. PCP was a popular street drug in the late 1960s (e.g., "angel dust") and was also known as "crystal," "killerjoints," or "supergrass" when smoked with tobacco, parsley, mint, oregano, or marijuana. It is rapidly absorbed via ingestion, snorting, injection, or smoking. In recreational use, its dose ranged from 1 to 10 mg per dose; toxic psychosis occurred with more than 5 mg. It is cleared by both hepatic (major) and renal (minor) elimination (1).

Ketamine (2-[2-chlorophenyl]-2-methylaminocyclohexanone), synthesized from PCP in the 1960s, has been used as a pediatric and veterinary anesthetic since 1970. Recreational ketamine abuse began in 1980 in association with thefts from veterinary clinics but has declined since then. Ketamine is used today as a short-term anesthetic (Ketalar) and is still a popular hallucinogenic, sometimes utilized as a "date-rape" drug (2). Street names include "K," "K-blast," "kit-kat," "lady K," and "special K," "vitamin K." Its pharmacodynamic effects are similar to those of PCP, but with less potency, a smaller volume of distribution, and a shorter half-life and duration of action. Like PCP, it is rapidly absorbed and has a rapid onset of action via ingestion, snorting, injection, or smoking. The

dose varies from 10 to 500 mg. PCP is hepatically metabolized to bioactive norketamine, which is eliminated by the kidney (3). PCP and ketamine have similar chemical structures (eFig. 347.1). Both drugs bind to the PCP binding site on the N-methyl-D-aspartate (NMDA)-receptor complex (dissociative anesthetic effects via noncompetitive inhibition of calcium influx) (4). At sympathetic nerve terminals, both drugs act as catecholamine reuptake inhibitors. At higher doses, these drugs stimulate σ-opioid receptors (causing lethargy, obtundation, or coma) and variably stimulate muscarinic, dopaminergic, γ-aminobutyric acid (GABA)-ergic, and non–σ-opioid receptors, possibly by modulation of potassium conductance (1).



Ketamine



Phencyclidine (PCP)

eFIGURE 347.1

CLINICAL PRESENTATION

Effects begin within minutes after administration, lasting 8 to 24 hours for PCP and 30 minutes to 4 hours for ketamine. The effect is of longer duration in patients with impaired hepatic or renal function. Psychological dependence and tolerance may occur. Significant mental impairments are common but because there are minimal respiratory effects, deaths from direct effects are rare (2,5,6). Traumatic injuries and deaths from drug-related behavior are common, however (6).

PCP effects include euphoria, severe auditory hallucinations, short-term memory impairment, visual distortions, aggressiveness, and disconnection from reality. There may also be extreme behavioral swings between catatonia and excessive agitation, severe violence, combativeness, and "superhuman strength" (5). The superhuman strength is thought to come from its effect as a "dissociative anesthetic" where the patient does not feel pain associated with exertion or injury. Children exhibit primarily motor effects, with less aggressive behavior (7). Acute psychosis with PCP is clinically indistinguishable from schizophrenia. Other findings include ataxia, dystonia, hypertonia, seizures, and sympathomimetic effects. Hypertension may be associated with intracranial hemorrhage and focal neurologic signs, with or without associated trauma (8). Hyperthermia occurs from excessive muscular rigidity, hyperactivity, or sustained seizures. Rhabdomyolysis and crush injury can occur from agitation and struggling against restraints. Lacrimation and hypersalivation is secondary to cholinergic stimulation. The pupils are paradoxically small because of cholinergic and opioid receptor stimulation. Nystagmus occurs in over 50% of PCP overdoses and may be horizontal, vertical, or rotatory (5).

Ketamine's effects are less severe than those of PCP. There is dose-dependent perception disturbance, with mild agitation (8). A "floating" feeling is described, with prolonged, numbing, out-of-body experiences and perception of paralysis—the so-called "K-hole." (2). Impaired attention span, pain perception, and memory; miosis, nystagmus, ataxia, and mumbling speech; and delirium, hallucinations, tachycardia, and hypertension can also occur. Ketamine is a mild bronchodilator, but also induces bronchorrhea and sialorrhea (2).

DIFFERENTIAL DIAGNOSIS

PCP intoxication should be suspected with any acute onset of psychosis, especially when there is fluctuating mental status. Clues to PCP include violence, indifference to pain, and difficulty

restraining the patient, although these can be seen with other intoxications such as cocaine and methamphetamines.

Both drugs mimic adrenergic agents, anticholinergic agents, and opiates. There is tachycardia and hypertension, but accompanied by miosis, nystagmus, and hypersalivation. Withdrawal from these agents can mimic ethanol and sedative–hypnotic withdrawal (5,6).

Because PCP or ketamine may be taken with other drugs, additional signs or symptoms may be present (9). Cyanide poisoning should be considered after smoking PCP. Occult traumatic injury should always be considered (8). Acute psychiatric illness is always in the differential, especially in patients with a similar history.

ED EVALUATION

History should include the time, amount, and route of exposure, and circumstances and events prior to arrival. Additional details should be obtained from police and sources other than the patient. A physical and mental status examination should focus on vital signs (including temperature), neurologic findings, evidence of trauma, pulmonary aspiration, and complications of injection drug use. An early temperature assessment can identify patients who need immediate cooling. Serum electrolytes, complete blood count, blood gas, creatine phosphokinase (CPK), and serum ethanol level can assist in supportive care for lethargic, comatose, or extremely violent patients. A rapid urine drug screen may confirm the presence of PCP but many screens do not test for PCP. Ketamine is not reliably detected on rapid screens. False-positive testing for PCP can occur with ketamine and dextromethorphan (9). Send-out quantitative PCP or ketamine levels do not correlate with toxicity and are not useful. Urine testing for PCP or ketamine by gas chromatography/mass spectroscopy can confirm exposure but the patient will have recovered long before the results are available. Urinalysis may be positive for hemoglobin, suggesting rhabdomyolysis (6), but patients who are at risk should also have CPK measured. Brain computed tomography (CT) and other imaging

may be necessary when there are signs of head injury or other trauma (8).

KEY TESTING

- Urinalysis and CPK for patients at risk for rhabdomyolysis
- Imaging may be needed for patients with concurrent trauma
- Toxicology screening and quantitative testing are not helpful clinically
- Electrolytes, blood gases, CBC, and ethanol level may be helpful for general supportive care

ED MANAGEMENT

Because of unpredictable violent behavior, adequate security personnel should be present when these patients arrive. Advanced life support measures are followed by aggressive supportive care. Comatose patients require rapid bedside glucose, thiamine, and naloxone. Naloxone does not bind to σ-opioid receptors so opioid effects are not reversed and a poor response to naloxone may suggest PCP or ketamine toxicity.

Violent and aggressive behavior may worsen acidosis and hyperthermia, and places patient and staff at risk for injury. Agitation may be attenuated by a darkened room with minimal sensory stimulation, but immediate physical restraint may be necessary to avoid self-harm but chemical restraint should be started as soon as safely possible with intravenous (IV) diazepam (0.1 mg/kg/dose) or lorazepam (0.1 mg/kg/dose). The dose may need to be titrated to effect every 5 to 10 minutes. IV access may be delayed and so haloperidol 5 to 10 mg or droperidol 2 to 10 mg intramuscular (IM) (0.5 mg for children) may be given every 30 to 60 minutes. These are generally effective but butyrophenones may exacerbate hypertonia, as well as the risk of QT interval prolongation and possible torsade de pointes (10) Lorazepam can also be given IM. Phenothiazines are not recommended (may lower seizure threshold, exacerbate hyperthermia, contribute to systemic acidosis, and induce hypotension). Neuromuscular paralysis with

intubation may be necessary in refractory cases of violent psychosis (6).

Seizures should be treated with benzodiazepines: diazepam 0.1 to 0.2 mg/kg/dose IV, lorazepam 0.05 to 0.1 mg/kg IV, or midazolam 0.1 to 0.2 mg/kg IV. Refractory seizures may be treated with phenobarbital 10 to 15 mg/kg IV. Phenytoin is ineffective.

Severe hypertension is generally transient, but if it is symptomatic may be treated with esmolol 0.025 to 0.1 mg/kg/min IV or nitroprusside 2 to 10 μg/kg/min IV. Hyperthermia should be treated with evaporative cooling and sedation, and with chemical paralysis in refractory cases (see Chapter 360 Heat-related illness). Patients with rhabdomyolysis should be given IV saline to restore and maintain adequate urine flow, along with standard management interventions to prevent complicatons.

Activated charcoal can be administered, but is often unpractical because time of ingestion is unknown and the patient is uncooperative. Neither continuous gastric suctioning nor multiple-dose activated charcoal enhance drug clearance or shorten the duration of symptoms (1).

Urinary acidification with ammonium chloride theoretically enhances PCP and ketamine excretion, but does not shorten the duration of toxicity, can worsen acidemia, and may promote renal failure by inducing tubular myoglobin precipitation. Hemodialysis or hemoperfusion do not enhance elimination because of high protein binding and large volumes of distribution.

CRITICAL INTERVENTIONS

- Obtain a core temperature, ABG, and serum CPK to assess for hyperthermia, acidosis, and rhabdomyolysis, respectively, in patients with agitation, psychosis, and seizures.
- Administer IV benzodiazepines or haloperidol for agitation so as to avoid physical restraint.
- Administer IV benzodiazepines and barbiturates for seizures and neuromuscular hyperactivity.

- Treat hyperthermia with evaporative cooling, sedation, and neuromuscular paralysis as needed.
- Administer saline, with or without mannitol and sodium bicarbonate, to patients with rhabdomyolysis.
- Administer IV esmolol or nitroprusside for persistent, symptomatic, or severe hypertension.

DISPOSITION

Patients with a history and examination consistent with drug use and without injury can be sedated and observed, and may be discharged if their condition improves in the ED. Ketamines often resolve in the ED, but PCP patients may need to be admitted for more prolonged observation. Neurosurgical, orthopedic, and trauma consultation may be necessary for physical trauma associated with intoxication. Patients with continued altered mental status after 4 to 6 hours, major trauma, or hemodynamic instability should be transferred to a critical care setting. Patients with persistent psychiatric symptoms after resolution of drug toxicity should be referred to a psychiatrist. All patients should be referred for substance abuse counseling.

Common Pitfalls

- Exposure of healthcare personnel to harm because of inadequate preparation for security, restraint, and sedation.
- Delay in sedation and control of agitation.
- Exclusion of PCP or ketamine intoxication on the basis of a negative drug screen.
- Failure to appreciate that ketamine and dextromethorphan can result in a false-positive PCP on immunoassays.
- Failure to consider the possibility of intracranial hemorrhage and trauma in patients with altered mental status.

CHAPTER 348

Amphetamines and Stimulants

Michael J. Lynch and Anthony F. Pizon

Sympathomimetic agents represent a wide range of legal and illegal drugs. As the name implies, the physiologic response to these medications is a result of stimulation of the sympathetic nervous system. In therapeutic doses, these medications are used as stimulants, appetite suppressants, attention-deficit hyperactivity disorder (ADHD) therapy, decongestants, and bronchodilators. However, in supratherapeutic ingestions, patients may suffer cardiovascular and central nervous system (CNS) toxicity.

Sympathomimetics are typically divided into direct- and indirect-acting drugs. Direct-acting sympathomimetics (e.g., albuterol) bind postsynaptic receptors, stimulating them directly. Indirect-acting sympathomimetics (e.g., methamphetamine and amphetamine) raise synaptic concentrations of biogenic amines (norepinephrine, epinephrine, dopamine, serotonin) by (a) enhancing transmitter release from presynaptic vesicles, (b) inhibiting neurotransmitter reuptake, and (c) decreasing transmitter degradation. Mixed-acting agents such as dopamine and pseudoephedrine stimulate receptors both directly and indirectly (1).

Several different neurotransmitters may be affected, leading to variation in clinical presentation, therapeutic use, and toxicity. Stimulation of α- and β-receptors by epinephrine and norepinephrine leads to tachycardia and vasoconstriction, and central norepinephrine release leads to anorexia and CNS excitation. Excess dopaminergic stimulation plays a role in the addictive nature

of many of these drugs. Dopamine-mediated glutamate activity coupled with γ-aminobutyric acid (GABA) inhibition leads to seizures as well as "crack dancing," choreoathetoid-movement disorders that occur with acute intoxication (1). Euphoria and altered perception have been attributed to increased serotonin.

"Stimulants and street drugs" were responsible for 65,856 human exposures reported to US poison centers in 2011 and was associated with nearly 6% of all fatalities reported (2). Abuse of both legal and illegal stimulants is a growing problem that will be encountered by emergency physicians.

DRUGS OF ABUSE

Amphetamines are phenylethylamine derivatives, structurally similar to catecholamines, with different enantiomers and chemical substitutions that account for the variety of clinical effects. Amphetamines are a class of drugs that should not be confused with the drug amphetamine, which has a very specific structure and function. Drugs in the class of amphetamines are all based on the phenylethylamine structure. Compared to amphetamine, *methamphetamine* causes more powerful cardiovascular and CNS stimulant effects and *methylenedioxymethamphetamine (MDMA)* also known as ecstasy, is a much more potent serotonergic drug. Amphetamine metabolites also weakly inhibit monoamine oxidase.

MDMA and several of its derivatives are available as oral formulations, and methamphetamine is typically ingested or injected ("crank" or "speed"). Methamphetamine may also be smoked when in its purest crystalline formulation ("ice" or "crystal meth"). Metabolism takes place primarily by the liver cytochrome p450 system with renal elimination. Amphetamines are bases, and the elimination half-life of the drug is dependent upon urine pH, with more rapid elimination in acidic urine. Half-lives range from roughly 5 to 10 hours for MDMA to 12 to 34 hours for methamphetamine (3). These drugs are manufactured illegally and may be significantly contaminated with impurities. Moreover, because of the volatile nature of the chemicals involved in

production of methamphetamine, explosions occurring during their synthesis pose a significant chemical hazard to the public, law enforcement officers, and emergency medical service (EMS) providers.

Cathinone is the active ingredient in khat (*Catha edulis*), a plant that is chewed or brewed into tea in eastern and central Africa and the Middle East for its stimulant effect. In 2009, the United States experienced an explosion of cathinone-derived drugs sold as legal highs and marketed as "*bath salts,*" "plant food," and "stain remover." Though largely made illegal on either the state and/or federal level, cathinones are still widely abused with similar chemical structure to methamphetamine and MDMA. Commonly abused cathinone derivatives include mephedrone, methcathinone, and methylenedioxypyrovalerone (MDPV).

PHARMACEUTICALS

Prescription amphetamines used to treat ADHD, including methylphenidate and amphetamine/dextroamphetamine, are widely abused. Much of this abuse is related to the fourfold increase in amphetamine prescriptions since the late 1980s, leading to greater availability (4), so that 15% of 12th graders admit to their illicit use. These medications have effects and pharmacokinetics similar to those of methamphetamine but are significantly less potent. Selegilene, a monoamine-oxidase inhibitor (MAOI) used in the treatment of Parkinson disease, is metabolized to L-methamphetamine, but there are no reports of overdose.

Phentermine, diethylpropion, and mazindol are centrally acting stimulants that have direct anorectic effects. These drugs are available as schedule IV prescription weight loss drugs. Fen-Phen, which contained phentermine in combination with the serotonergic drug fenfluramine, was voluntarily taken off the market because of its association with valvular heart disease and primary pulmonary hypertension.

Oral and topical decongestants, as well as some weight loss drugs, act via direct and indirect effects at α- and/or β-adrenergic

receptors to induce vasoconstriction and decreased localized edema. *Phenylephrine* is a potent direct $\alpha_{1,2}$-receptor agonist while phenylpropanolamine is a direct- and indirect-acting $\alpha_{1,2}$ agonist. Toxicity of these medications includes hypertension with reflex bradycardia caused by the lack of β-adrenergic stimulation. *Ephedrine* and its less potent *d*-isomer, *pseudoephedrine,* are both direct and indirect-acting $\alpha_{1,2}$- and $\beta_{1,2}$-adrenergic–receptor agonists. Consequently, toxicity consists of both tachycardia and hypertension, as seen with other sympathomimetic stimulants. CNS stimulation and seizures are also reported with these classes of decongestants. Because of its association with intracranial hemorrhages, *phenylpropanolamine* was removed from the market by the FDA (5). The sale of ephedrine, although not illegal, has also been restricted in many states because of its abuse potential and reported toxicity.

Another class of decongestants is the *imidazolines* (oxymetazoline, tetrahydrozoline, and naphazoline). Typically, the imidazolines are used as topical decongestants in nasal sprays and eye drops, but they can cause systemic toxicity. These drugs are central and peripheral α_2-agonists like clonidine and therefore lead to peripheral α-mediated adrenergic symptoms, including hypertension with reflex bradycardia, followed by centrally mediated sympatholysis, bradycardia, and hypotension. CNS and respiratory depression caused by central α-agonism can also occur. See Chapter 322.

Prescription sympathomimetics also include β_2-agonists such as *albuterol, salmeterol, and terbutaline.* These medications are used to treat asthma and bronchospasm but are rarely abused. Nevertheless, in therapeutic and supratherapeutic doses, these drugs may lead to supraventricular or sinus tachycardia, increased inotropy, and hypotension secondary to β-agonism without α-agonism. Other toxic effects include hypokalemia, rhabdomyolysis, nausea, and vomiting. *Clenbuterol,* a long-acting β_2-adrenergic agonist, is abused as a performance-enhancing drug as well as used as an adulterant in heroin (6). Heroin overdoses that present with tachycardia,

hypotension, and hypokalemia are suggestive of clenbuterol exposure.

HERBAL SUPPLEMENTS

Herbal supplements are extremely popular adjuncts for weight loss regimens in the United States. *Ma huang,* a Chinese herbal supplement, contains ephedra alkaloids that comprise six different sympathomimetic amines, including ephedrine and pseudoephedrine. Because of the incidence of significant cardiovascular toxicity, including stroke, cardiac arrest, and MI, the sale of ephedra was banned in 2005 (7). As a result, many herbal supplements have been reformulated to include bitter orange extract (*Citrus aurantium*), which contains synephrine, an isomer of the direct-acting α-agonist phenylephrine. Cases of variant angina, cerebral ischemia, and compartment syndrome with rhabdomyolysis and renal failure have been reported in association with synephrine use (8). A careful history, including over-the-counter medications and herbal supplements, must be taken in patients with suspected sympathomimetic toxicity.

CLINICAL PRESENTATION

Patients presenting to the ED with acute sympathomimetic toxicity typically display tachycardia, hypertension, diaphoresis, and hyperactivity. Pupils may be normal or dilated. Some patients exhibit psychotic behavior. Tremor and hyperreflexia can progress to seizures. In cases of severe toxicity, hypertension can lead to cerebral ischemia or intracerebral hemorrhage (7). Because the hypertension is usually acute, it can cause neurologic injury at pressures lower than those typically seen in patients with chronic hypertension; this is presumably caused by the lack of autoregulatory mechanisms. Sustained increases in muscle activity and seizure may result in rhabdomyolysis with significant elevation in creatine kinase (CK) and myoglobinuric renal failure. Patients with continued untreated muscle activity are at risk for severe metabolic acidosis and hyperthermia. Hyperthermia is a late and

ominous finding in patients suffering from sympathomimetic toxicity.

Common mental status changes include euphoria, agitation, psychosis, anxiety, and confusion. These changes are usually related to the expected drug effects, but other causes such as intracranial hemorrhage, ischemia, or cerebral edema must be considered. Hyponatremia related to markedly increased free water intake and elevated antidiuretic hormone (ADH) levels may be seen in patients who have been "clubbing" or "raving" (3). Bruxism, or jaw clenching and teeth grinding, occurs with MDMA (ecstasy) ingestion (3).

Amphetamine and other sympathomimetics have been associated with acute myocardial infarction (MI), supraventricular and ventricular tachydysrhythmias, and cardiomyopathy with heart failure in a variety of age groups (3,7). Myocardial ischemia is thought to be related to vasospasm rather than occlusive disease. Chronic use of sympathomimetic drugs, even in therapeutic doses, has led to elevations in blood pressure and heart rate. Long-standing amphetamine abuse has also been associated with vasculitis that is responsive to treatment with immunosuppressants.

Sympathomimetic drug use and abuse can cause significant toxicity, disability, and death. Recognition of the disease process and rapid and aggressive treatment are necessary to prevent progression of symptoms.

DIFFERENTIAL DIAGNOSIS

Sympathomimetic toxicity should be considered in any patient with some or all of the clinical findings described previously. In particular, young patients with intracerebral hemorrhage, myocardial ischemia/infarction, arrhythmia, severe hypertension, or altered mental status should be interviewed with particular emphasis on legal and illegal drug use. However, a variety of toxicologic and organic disease processes may produce similar signs and symptoms. Toxicity from anticholinergic agents, cocaine, phencyclidine, MAOI interactions, and serotonin syndrome may

produce a similar clinical picture. Classically, anticholinergic toxicity has dry skin while the skin with sympathomimetic symptoms should be clammy. Withdrawal syndromes, as seen with alcohol, clonidine, γ-hydroxybutyrate (GHB), or sedative–hypnotics, should also be considered.

The differential diagnosis of sympathomimetic toxicity also includes thyroid storm, pheochromocytoma, infection, nondrug-induced intracerebral hemorrhage, ischemic stroke or seizure, brain tumor, MI, aortic dissection, and psychiatric disease.

ED EVALUATION

The initial evaluation should focus on the vital signs. The sympathomimetic poisoned patient develops tachycardia, hypertension, and hyperthermia. Hyperthermia is the most important determinant of mortality, and accurate temperature measurement should be a priority. An axillary temperature is not adequate for these patients, and a rectal or esophageal measurement is best. Once the vital signs have been addressed, a neurologic assessment is paramount. Hallucinations, agitation, dystonias, and seizures are noted in some patients. Choreoathetosis from excessive dopamine stimulation in the basal ganglia is often referred to as "crack dancing" but is seen with other sympathomimetic drugs. "Bath salts" commonly present with agitation and aggression, and symptoms may be prolonged after the abuse of long-acting cathinone derivatives like MDPV. The exact constellation of findings depends upon the specific sympathomimetic drug involved.

Laboratory testing includes electrolytes, blood urea nitrogen (BUN), creatinine, total CK, and urinalysis. These tests are important for the assessment of hydration, hyponatremia from excessive hypotonic water intake during periods of excessive drug abuse, rhabdomyolysis, and signs of acute kidney injury from myoglobinuria. An electrocardiogram (ECG) and troponin may be helpful with chest pain, to measure QRS and QTc intervals for potential ventricular dysrhythmias and along with continuous monitoring, to monitor response to treatment. Additionally, QRS

and QTc interval evaluation is critical to identifying potential for ventricular dysrhythmias and response to treatment. A head computed tomography (CT) scan may be helpful, if there are signs of trauma or intracranial hemorrhage, but is likely to be of low yield in most patients. A urine drug screen (e.g., EMIT assay) is not considered a useful diagnostic test. A negative amphetamine screen on an EMIT assay does not eliminate a sympathomimetic as the cause of symptoms, because many sympathomimetic drugs do not produce positive tests. Similarly, a positive test does not mean the patient took an amphetamine or amphetamine-like drug immediately prior to arrival, because an amphetamine screen may remain positive for days after drug use. Clinical suspicion for sympathomimetic poisoning should be based on history and physical examination.

KEY TESTING

- Immediately obtain vital signs with an emphasis on an accurate temperature.
- Electrolytes, BUN, creatinine, and total CK are used to evaluate for hyponatremia, dehydration, acute kidney injury, and rhabdomyalysis.
- An EKG is useful for the evaluation of dysrhythmias or cardiac ischemia.

ED MANAGEMENT

The initial management of sympathomimetic poisoning should focus on treatment of the vital signs. Because hyperthermia is the most important determinant of mortality, aggressive cooling should be initiated early. Any elevation in temperature should be taken seriously, and a reasonable goal is to reduce temperature to below 38°C. Because hyperthermia is a result of excessive muscle contraction or shivering, sedation or even paralysis should precede cooling measures for cooling to be more effective (see Chapter 360).

Chemical sedation treats hyperthermia and is also an effective treatment of other vital-sign abnormalities (e.g., tachycardia and

hypertension) and agitation. Benzodiazepines are the best first-line agents in these cases. Benzodiazepines should be quickly titrated to the point of making the patient noticeably comfortable; when used by themselves, they rarely result in airway compromise. In addition, benzodiazepines treat possible seizures and other syndromes that may be included in the differential diagnosis (e.g., GABA-agonist withdrawal or other drug-induced delirium). Reasonable intravenous (IV) adult starting doses are diazepam 5 to 10 mg or lorazepam 2 to 4 mg every 5 to 10 minutes. Besides benzodiazepines, sympathomimetic-induced delirium may also benefit from haloperidol (9). Antipsychotics like haloperidol or droperidol antagonize central dopamine receptors and may offer additional benefit by a mechanism distinct from that of benzodiazepines. In particular, choreoathetosis associated with sympathomimetic poisoning will disappear after antipsychotic administration. Antipsychotics should be used with caution, because they can lower the seizure threshold, can lead to dysrhythmias from QT prolongation, and may alter temperature regulation. Haloperidol 5 mg IV, with increasing doses every 20 minutes, can be an effective addition to benzodiazepines.

At times, agitation and aggression may be prolonged and difficult to manage with benzodiazepines and antipsychotics. This is most commonly observed in patients who abuse “bath salts.” In these circumstances, pharmacotherapy should be rapidly titrated but under these extreme presentations, appropriate management includes intubation and use of general anesthetics like propofol (Diprivan).

Hypertension is usually controlled by sedatives alone. However, when additional treatment is needed, nitroglycerin (5 to 400 μg/min IV), phentolamine (5 to 15 mg IV every 20 minutes), and nitroprusside (0.25 to 10 μg/kg/min) are good adjuncts. It is difficult to specify a target blood pressure for treatment, but a pressure $<$180/110 mm Hg is generally recognized as a reasonable goal while avoiding overtreatment. If there is evidence of hypertensive encephalopathy or intracranial hemorrhage, more aggressive treatment may be necessary. β -Blockers should be

avoided. Paradoxical hypertension may result from blockade of β_2-mediated vasodilation and unopposed α_1-adrenergic vasoconstriction. Coronary artery vasospasm has been noted when propranolol is used after cocaine administration in human volunteers (10).

Rhabdomyolysis requires aggressive fluid resuscitation, with a target urine output of 1 to 2 mL/kg/hr. Sympathomimetic-poisoned patients are often volume depleted, and routine fluid administration is good practice in this population.

Gastrointestinal (GI) decontamination is rarely of benefit. In patients who present after the onset of symptoms, activated charcoal administration is not expected to be helpful. The exception is in "body stuffers." Patients who have ingested poorly packaged stimulants to hide contraband from the police may benefit from activated charcoal because they may be subject to absorption (often erratic) of the drug. Body stuffers who present before the onset of symptoms should routinely receive activated charcoal. Other forms of GI decontamination are not routinely recommended for this patient population. "Body packers" are smuggling well-packaged stimulants and are treated differently.

CRITICAL INTERVENTIONS

- Measure the temperature in a timely manner in patients with agitation, hyperactivity, seizures, and abnormalities of other vital signs.
- Rapidly sedate and cool patients with hyperthermia while instituting core body temperature monitoring.
- Use benzodiazepines to treat hyperthermia, hypertension, and tachycardia from sympathomimetic poisoning.

DISPOSITION

Because the duration of toxicity is often brief, patients with mild signs or symptoms may be monitored in the ED. Observation and monitoring of vital signs is advised for a minimum of 6 hours or until symptoms abate. Patients with persistent headache or

neurologic signs may require a head CT scan. Patients with persistent CNS stimulation or vital-sign abnormalities should be admitted to an intensive care unit. The most ill patients, who present with hyperthermia, often require prolonged hospitalization for treatment of rhabdomyolysis and the associated renal failure. However, most cases require only short hospital stays for benzodiazepines, IV fluids, and monitoring of vital signs.

Common Pitfalls

- Failure to consider sympathomimetic toxicity in the differential diagnosis of tachycardia, hypertension, intracranial hemorrhage, and cerebral or myocardial ischemia.
- Failure to appreciate that headache, even without focal neurologic signs, may be the result of intracerebral hemorrhage.
- Failure to identify hyponatremia as a cause of cerebral edema and altered mental status.
- Failure to obtain a CK to check for rhabdomyolysis in patients with agitation and hyperthermia.
- Failure to appreciate that bradycardia in patients with hypertension as a result of sympathomimetic abuse is a normal reflex response. Treating bradycardia with atropine in this situation could aggravate hypertension.

PART 10 • MISCELLANEOUS AGENTS AND CONDITIONS

CHAPTER 349

Biologic Warfare Agents

Jeffrey R. Suchard

Biologic weapons are microorganisms or toxins derived from microorganisms that are intentionally used to cause death, disability, or damage to humans, animals, or plants. Although small-scale biologic warfare (BW) has been practiced since antiquity, it is only in the past several decades that such weapons could be mass-produced and have the potential to cause widespread casualties. Even limited releases of BW agents can have major public health impact, causing widespread fear and affecting far more than simply the medical disease, as with the 2001 outbreak from anthrax spore-contaminated mail (1). Biologic weapons may hold particular appeal to terrorists, because the investment is less than for other weapons of mass destruction, although the potential morbidity and mortality remain high.

BW agents fall into three general categories: (1) bacteria, (2) viruses, and (3) toxins. The first two categories are infectious agents, although these diseases are now rarely encountered in clinical medicine (e.g., anthrax, plague, Q fever, viral equine encephalitis) or no longer occur naturally (e.g., smallpox). Although most of the diseases caused by infectious BW agents cannot be contracted by interaction with the patient, some (e.g., pneumonic plague, smallpox, viral hemorrhagic fevers [VHFs]) are able to cause secondary casualties, necessitating careful precautions and patient isolation to prevent uncontrolled outbreaks. Toxins are not transmissible, because they cannot reproduce, effectively making them chemical weapons from a biologic source.

The most efficient method of producing mass casualties from BW agents is by aerosol inhalation. The ideal aerosol particle size to promote deposition in the respiratory tract is 1 to 5 μm, which corresponds to the size of individual bacteria or spores and would not be detectable by sight, smell, or taste. A likely scenario following BW-agent exposure would be an epidemic of persons with a nonspecific acute respiratory syndrome (i.e., fever and cough).

Although chemical weapons produce acute symptoms within minutes to hours, the effects from BW agents may take many hours, days, or sometimes weeks to manifest, depending on the incubation period of the agent. Thus, the epidemic curve of case incidence will be more difficult to detect than for chemical weapons, as patients will present less tightly clustered in time and location. An obvious ploy to avoid early detection would be to release an agent causing an endemic infection (or disease resembling an endemic infection) during its season of peak incidence. For example, in areas where bubonic plague is endemic, an intentional release of *Yersinia pestis* may elude detection until many more cases develop. Similarly, the early symptoms of inhalational anthrax could easily be missed during influenza season, and it might not be until an unusually high morbidity was evident that a biologic weapon's attack was suspected. On the other hand, even a single case of smallpox or a VHF in a nonendemic area would immediately raise suspicion of a BW attack.

High-risk potential BW agents include smallpox, anthrax, plague, botulism, tularemia, and several hemorrhagic fever viruses. These agents are easily disseminated or transmitted from person to person, cause high mortality with the potential for major public health impact, and may cause panic and social disruption requiring special action for public health preparedness. Moderate-risk agents include Q fever, brucellosis, the equine encephalitis viruses, ricin, and staphylococcal enterotoxin B. Although other biologic agents could potentially be used as weapons, this chapter will focus on agents of greatest concern for causing mass casualties.

ANTHRAX

Bacillus anthracis is a spore-forming gram-positive rod. Anthrax spores are found in the soil in many parts of the world and mostly cause disease among grazing animals. Human anthrax generally occurs in farmers, ranchers, and among workers handling animal carcasses, hides, hair, and bones. Different clinical forms of anthrax occur depending on the route of exposure. (1) Cutaneous anthrax occurs from direct inoculation of spores into the skin via abrasions and accounts for approximately 95% of human cases. (2) Gastrointestinal anthrax follows the ingestion of insufficiently cooked meat of infected animals. (3) Inhalational anthrax occurs after exposure to aerosolized spores. The inhaled spores are taken into the lymphatic system, where they germinate, reproduce, and cause swelling of the mediastinal lymph nodes. Although this form of anthrax is very rare, it is closely associated with occupational exposures called woolsorter's disease. Inhalational anthrax is the most likely form of a BW attack, because the spores would be most effectively disseminated by aerosol. In the 2001 anthrax attack in the United States, 11 cases were inhalational (all five fatalities were in this group), and 12 were cutaneous (2).

PLAGUE

Y. pestis is the gram-negative bacillus that causes plague. Like anthrax, plague occurs in different clinical forms. (1) Bubonic plague is the most common naturally occurring form of the disease, transmitted from the bites of infected fleas. (2) Pneumonic plague may be secondary to septicemia during cutaneous plague seeding the lungs, or it may occur primarily from the inhalation of infected respiratory droplets or an intentionally disseminated BW aerosol. Primary pneumonic plague would be the expected form of the disease from an aerosol BW agent release and should occur in the absence of bubonic plague (3).

TULAREMIA

Francisella tularensis is a small, aerobic, gram-negative coccobacillus. Tularemia may occur in (1) ulceroglandular or (2) typhoidal forms, depending on the route of exposure. Ulceroglandular tularemia is

more common, occurring after skin or mucous membrane exposure to infected animal blood or tissues. Exposure to aerosolized bacteria may result in typhoidal tularemia with prominent respiratory symptoms (4).

SMALLPOX

Variola, the virus that causes smallpox, is a large DNA-bearing orthopoxvirus with a host range limited to humans. Naturally occurring smallpox was eradicated by a global vaccination campaign in the 1960s and 1970s, yet stocks of the virus still remain in labs in the United States, Russia, and possibly elsewhere. Smallpox remains a significant potential BW threat, because a large portion of the current population has not been immunized and the degree of immunity conferred by remote vaccination is not clear. Transmission occurs through inhalation of droplets or aerosols but may also occur through contaminated fomites (5).

VIRAL HEMORRHAGIC FEVERS

Several diverse RNA viruses produce VHF, an acute febrile illness with increased vascular permeability that cause bleeding manifestations in the more severely affected. The VHF agents of greatest concern are those that may be intentionally disseminated by an aerosol route; these include the Marburg, Ebola, and Hanta viruses and those causing Lassa fever, yellow fever, Rift Valley fever, and Crimean-Congo hemorrhagic fever (6).

BOTULISM

Botulinum toxin would most likely be disseminated through food contamination or by aerosol. Either method would result in the clinical syndrome of botulism (see Chapter 352) (7). Rarely, inhalation botulism from laboratory accidents has occurred.

Several clinical syndromes may occur from exposure to BW agents. Because inhalation of an aerosol is a likely method of exposure, development of an acute respiratory syndrome is common to many agents. Other syndromes include influenza-like illnesses, cutaneous lesions or ulcerations, fever with lymphadenopathy or arthralgias,

acute neurologic syndromes (with or without fever), and hemorrhagic diathesis. An individual case of illness from BW agent exposure may be very difficult to detect, because many commonly occurring diseases also fit into such clinical syndromes. It is quite likely that a BW agent attack will be detected by the presence of an unusual epidemiologic curve, when a cluster of patients with unusual findings or with a fulminant clinical course present within a short period of time.

CLINICAL PRESENTATION

The clinical presentation of patients exposed to BW agents will obviously vary depending on the agent.

Cutaneous anthrax results in a black eschar with significant surrounding edema at the site of skin entry. Most lesions will heal spontaneously, although 10% to 20% of untreated cases progress to septicemia and death. Cutaneous anthrax fatalities are rare with antibiotic therapy. Gastrointestinal anthrax causes nausea, vomiting, fever, abdominal pain, and mucosal ulcers, which can cause hemorrhage, perforation, and sepsis; mortality is high (2).

Inhalational anthrax has an incubation period of one to six days. Patients then develop fever, malaise, fatigue, nonproductive cough, and mild chest discomfort. Symptoms may abruptly progress to severe respiratory distress with dyspnea, diaphoresis, stridor, and cyanosis. Bacteremia, shock, metastatic infection (meningitis occurs in approximately 50% of cases), and death follow within 24 to 36 hours. Inhalational anthrax is a mediastinitis, rather than a pneumonia. Chest radiography and computed tomography typically show mediastinal widening and pleural effusions, although pneumonic infiltrates are also reported (2).

Historically, the mortality rate from inhalational anthrax was nearly 100% once symptoms develop, even with antibiotics. Experience from the 2001 outbreak in the United States shows that over half of the patients with inhalational anthrax survived with aggressive supportive care and antibiotic therapy. Earlier hospitalization appeared to correlate with improved outcome (1).

Bubonic plague has an incubation period of 2 to 10 days preceding the onset of fever, malaise, and painful, enlarged regional lymph nodes (buboes). Septicemia may occur and can be accompanied by disseminated intravascular coagulation (DIC) and acral gangrene. Necrosis of the digits and nose seen with septicemic plague is a likely origin of the term “black death” (3).

Pneumonic plague has an incubation period of two to three days. The onset of disease is acute and often fulminant. Patients develop fever, malaise, and cough productive of bloody sputum, rapidly progressing to dyspnea, stridor, cyanosis, and cardiorespiratory collapse. Plague pneumonia is almost always fatal unless treatment is begun within 24 hours of symptom onset.

Ulceroglandular tularemia is characterized by local skin ulceration and associated lymphadenopathy, fever, chills, headache, and malaise. Typhoidal tularemia presents with fever, prostration, and weight loss without adenopathy. Exposure to aerosolized bacteria should result in typhoidal tularemia with prominent respiratory symptoms like a nonproductive cough and substernal chest discomfort. Chest radiographs may show infiltrates, mediastinal lymphadenopathy, or pleural effusions. A temporarily incapacitating infection is most likely (4), but fatalities may occur.

Smallpox has a 12- to 14-day incubation period. Initial symptoms include fever, malaise, and prostration with headache and backache. Oropharyngeal lesions appear first, shedding virus into the saliva. Two to three days after the onset of fever, a papular rash develops on the face and spreads to the extremities. The fever continues as the rash becomes vesicular and then pustular. The pustules scab over and eventually separate, leaving pitted and hypopigmented scars. The mortality rate of smallpox can be as high as 30%, with death most commonly occurring during the second week of the illness (5).

VHF is characterized by fever, malaise, prostration, and hemorrhagic rash. Clinical features, such as the extent of renal, hepatic, and hematologic involvement, vary according to the agent involved. Mortality rates also vary, from $<1\%$ for Rift Valley fever up to 50% to 90% for the ebola virus (6).

Botulism results in multiple bulbar nerve palsies and a symmetric descending paralysis, with death occurring from respiratory failure (see Chapter 352). Onset of symptoms can occur within 24 to 36 hours or take several days (7).

DIFFERENTIAL DIAGNOSIS

Familiarity with the expected clinical syndromes produced by BW agents will aid in the differential diagnosis. An acute respiratory syndrome with fever may occur with inhalational anthrax, pneumonic plague, Q fever, hantavirus, and exposure to several other bacterial, viral, and fungal agents, as well as several common, endemic respiratory tract infections (e.g., influenza, the common cold, bronchitis, and community-acquired pneumonia). Patients with inhalational anthrax are more likely to have nausea or vomiting, tachycardia, elevated transaminases, low sodium levels, high hematocrit, low albumin levels, and normal white blood cell counts than those with influenza-like illnesses and community-acquired pneumonia, and patients with an influenza-like illness are more likely to have myalgias, headache, and nasal symptoms (8). The presence of pulmonary infiltrates on chest radiographs does not rule out inhalational anthrax, although anthrax patients are likely to also have an enlarged mediastinum and pleural effusions.

Agents producing cutaneous lesions include anthrax, plague, smallpox, tularemia, and many of the VHFs. Experience from the 2001 outbreak shows that cases of cutaneous anthrax may occur amidst other cases of inhalational anthrax. Small pustules or skin lesions may be found at the site of flea bites in cases of plague, whereas petechial rashes are common with VHFs. The individual lesions of smallpox closely resemble those from herpesvirus infections like chickenpox. Smallpox lesions will all be at the same stage of development, and they are found mostly in a centrifugal distribution (i.e., hand, feet, and face), in distinction from the typical centripetal pattern (chest and abdomen predominance) of chickenpox with patches of lesions at various stages of development.

An acute neurologic syndrome with fever suggests disease from a viral equine encephalitis, although other viral and bacterial BW

agents (Q fever, smallpox, typhus) may also have prominent headache, photophobia, and myalgias. A neurologic syndrome without fever from BW agents is likely to be as a result of botulism or other preformed toxins such as domoic acid, saxitoxin, or tetrodotoxin.

Botulism may resemble several other neurologic diseases, including myasthenia gravis, Guillain–Barré syndrome, tick paralysis, poliomyelitis, and organophosphate poisoning. Individual cases of such diseases occur but are rare so the simultaneous presentation of multiple patients with progressive paralysis should immediately suggest an environmental exposure, either to botulinum toxin or an organophosphate chemical warfare agent.

ED EVALUATION

It is likely that the first few cases will be missed but the best defense for detecting an abnormal pattern is an alert and curious clinician. Historical data to collect that might help the investigation include documentation of the time and place of BW agent exposure and if any other persons were potentially exposed and whether they are symptomatic. The time of onset, nature, progression, and severity of symptoms should be noted. The presence of any visualized suspect material (e.g., an unidentified white powder) should be determined, so that samples may later be taken by the proper authorities. Public health authorities may have to help and determine the exposure pattern and epidemiology. Respiratory precautions should be used by all clinicians when BW is in the differential diagnosis.

Physical examination should focus first on the vital signs and assessment of the patient's cardiopulmonary function and neuromuscular status to determine if emergent resuscitative efforts are necessary. Ideally, all patients should have continuous cardiac and oxygen saturation monitoring, although this may not be possible in a mass-casualty setting. Physical examination should be performed with particular attention to detecting pulmonary rales, diminished breath sounds, the presence and characteristics of any rash, lymphadenopathy, meningismus, and any neurologic deficits.

Patients with pulmonary symptoms should have a chest radiograph, looking for pulmonary infiltrates, mediastinal widening, and pleural effusions. Chest computed tomography was also used in several patients with inhalational anthrax in 2001 (1). Arterial blood gas analysis should also be considered.

Ill patients should have a broad panel of other laboratory tests, which may include a complete blood count, comprehensive metabolic panel, DIC screening, serologies, blood cultures, and Gram staining, depending on the suspected agent and clinical status of the patient. Laboratory personnel should be informed of the suspected pathogen(s). Antibiotic-susceptibility testing should be performed on all bacterial isolates, as strains may be deliberately modified by terrorists to enhance antibiotic resistance. Patients with suspected smallpox should have vesicle fluid from lesions cultured, and scrapings should be sent for electron microscopic analysis. Spirometry and arterial blood gas analysis should be performed on patients with suspected botulism to establish their ventilatory capacity.

Plague can be diagnosed by various staining techniques, immunologic studies, or culturing the organism from blood, sputum, or lymph node aspirate. *Y. pestis* appears as a "safety-pin" bipolar coccobacillus. Chest radiographs in pneumonic plague show patchy or consolidated bronchopneumonia. Leukocytosis with bandemia is common, as are markers of low-grade DIC and elevations of bilirubin and the hepatic transaminases. Diagnosing tularemia is often difficult, as the organism is hard to isolate by culture and the symptoms are nonspecific.

KEY TESTING

- Will vary depending on presenting clinical syndrome, but typically includes:
  - Chest x-ray, if pulmonary symptoms
  - CBC
  - CMP
  - Cultures: blood, sputum, lesion

- Pulmonary function tests (FVC, NIF) if patient has neuromuscular weakness

ED MANAGEMENT

Advanced life-support measures are instituted as necessary for patients requiring resuscitation. Unlike with chemical weapons, patient decontamination is rarely an issue with biologic weapons. Most BW agents, with the notable exception of anthrax spores, are degraded by sunlight and desiccation and do not survive well in the environment for more than 1 to 2 days. In the scenario of a covert BW agent release, by the time patients present for medical care several days after exposure, decontamination is futile and will only delay care. Even with an acute, efficiently dispersed release of a biologic weapon via aerosol (including anthrax spores), little surface contamination is produced. Clothing removal and a soap-and-water shower will remove 99.99% of any remaining organisms on the skin (9), and this may occur in the patients' home to reduce the strain on medical resources. Any grossly visible contamination with a BW agent, if present, should be removed by water irrigation, washing the skin with a sporicidal/bactericidal solution (e.g., 0.5% sodium hypochlorite, a 1:10 dilution of household bleach), and a final water rinse (9). If patient decontamination is performed at a healthcare facility, patients should remove their clothing and place it into sealed and labeled plastic bags, wash their hands, and shower thoroughly with soap and water.

For patients who present with symptomatic illness after a covert attack, decontamination is unlikely to be helpful, but healthcare provider protection is critical. Standard infection-control measures (gloves, gown, mask with eye shield) provide adequate protection from most agents. However, unless the offending BW agent is already known, it must be assumed that the patients have a potentially transmissible disease such as smallpox, pneumonic plague, or a VHF, which require airborne, contact, and droplet precautions. Patients with respiratory symptoms or a rash should be placed in a private negative-pressure room, and medical personnel caring for the patient should wear well-fitting N95 high-efficiency particulate air-filter

masks until the results of a more complete evaluation can guide treatment (9). If multiple casualties present at the same time, space limitations may require that patient isolation occurs in groups rather than individually.

Current treatment recommendations for anthrax rely primarily on ciprofloxacin and doxycycline (2) and are shown in Table 349.1. The currently recommended duration of therapy after bioterrorist exposure to anthrax is 60 days, to protect against the delayed development of inhalational anthrax which might occur.

TABLE 349.1
Antibiotic Treatment of Anthrax, Plague, and Tularemia[a,b]

Condition	Treatment
Cutaneous anthrax or	Ciprofloxacin 500 mg (10–15 mg/kg in children) PO twice daily, or
Postexposure anthrax prophylaxis	Doxycycline 100 mg (2.2 mg/kg in children) PO twice daily
	Amoxicillin 500 mg PO three times daily (80 mg/kg/d PO divided every 8 hrs in children) may be substituted if unable to tolerate other drugs
	Duration of treatment = 60 d with bioterrorism attacks
Inhalational anthrax	Ciprofloxacin 400 mg (10–15 mg/kg in children) IV every 12 hrs, or
	Doxycycline 100 mg (2.2 mg/kg in children) IV every 12 hrs plus one or two additional antimicrobials with in vitro activity against *Bacillus anthracis;* IV treatment initially, then switch to oral when clinically appropriate
	Duration of treatment = 60 d with bioterrorism attacks.
Active plague disease in contained casualty setting	Doxycycline 100 mg (2.2 mg/kg in children) IV every 12 hrs, or
	Ciprofloxacin 400 mg (10–15 mg/kg in children) IV every 12 hrs, or
	Chloramphenicol 25 mg/kg IV four times daily, or
	Streptomycin 1 g (15 mg/kg in children) IM twice daily, or
	Gentamicin 5 mg/kg IV once daily, or 2 mg/kg load and 1.7 mg/kg three times daily (2.5 mg/kg in children)
	Duration of treatment = 10 d
Postexposure plague prophylaxis or mass-casualty setting	Doxycycline 100 mg (2.2 mg/kg in children) PO twice daily, or
	Ciprofloxacin 500 mg (20 mg/kg in children) PO twice daily
	Duration of treatment = 7 d for postexposure prophylaxis; 10 d if disease present
Tularemia	Identical to treatment for plague, except duration of therapy = 14 d

[a]This table includes treatment regimens that are not FDA approved.

PO, by mouth; IV, intravenous; IM, intramuscular.

Effective vaccines against anthrax are available (10). Anthrax vaccine adsorbed (AVA) is used in the United States, which consists of a sterilized filtrate of an avirulent bacterial strain. As with any vaccine, local reactions to AVA occur in a minority of recipients (up to 20% with mild, local reactions), and self-limited systemic reactions occur even more rarely (<1.5%); serious adverse events are very rare. The dosage schedule for AVA is 0.5 mL subcutaneously at 0, 2, and 4 weeks and 6, 12, and 18 months, with yearly boosters. For emergency use after confirmed exposure, the vaccine is given as

soon as possible and again at 2 and 4 weeks, along with prophylactic antibiotics.

Respiratory droplet precautions are necessary in pneumonic plague until the patient has received antibiotics for at least 48 hours and shows clinical improvement. Antibiotic choices are similar to anthrax, with a high reliance on ciprofloxacin and doxycycline (Table 349.1). Antibiotics must be initiated early after exposure, because waiting for symptoms will result in extremely high mortality (3). Antibiotic treatment for tularemia is virtually the same as for plague (4).

The treatment of smallpox is largely supportive. Persons exposed to smallpox but without clinical disease should also be isolated and observed for the development of fever and rash for 17 days; this observation period may occur at home. The antiviral drug cidofovir may be beneficial in preventing smallpox, if administered early after exposure, but is probably no better than postexposure vaccination (5).

Vaccination before smallpox exposure or within 4 days after exposure significantly ameliorates subsequent illness. Vaccination against smallpox carries some risk for adverse reactions. The two most serious reactions are postvaccinal encephalitis and progressive vaccinia. Postvaccinal encephalitis occurs in about three cases per million primary vaccinees. Forty percent of cases are fatal, and some survivors are left with permanent neurologic sequelae. Progressive vaccinia can occur in immunosuppressed individuals and is treated with vaccinia immune globulin.

Most VHF agents carry the risk of secondary infection through droplet aerosols, and careful patient isolation is critical. Ribavirin has been used for some VHFs, but supportive care is the mainstay of therapy (6).

The mainstay of botulism therapy is supportive care, with ventilation if necessary. An equine antitoxin for passive immunization is available in the United States from the Centers for Disease Control and Prevention (CDC) through contact with local and state health departments. The antitoxin prevents worsening of disease caused by the toxin serotypes responsible for foodborne

illness (A, B, and E) but does not reverse established effects. An investigational heptavalent antitoxin against serotypes A through G has been developed (7).

CRITICAL INTERVENTIONS

- Wear gloves, gown, eye shield, and an N95 high-efficiency particulate air-filter mask when evaluating and treating patients with possible exposure to transmissible BW agents.
- If possible, place patients with respiratory symptoms or a rash in a private negative-pressure room.
- Contact appropriate local public health and law enforcement authorities in cases of suspected BW agent exposure.

DISPOSITION

All cases of suspected exposure to BW agents should be reported to local public health and law enforcement authorities. Unless the patient contracted their illness through unintentional exposure in a research laboratory, each case is potential evidence of a criminal bioterrorist act, requiring contact also with law enforcement agencies such as the local Federal Bureau of Investigation field office. Consultation with a local physician resource familiar with BW agents, such as an infectious disease specialist, military physician, toxicologist, poison control center, or the CDC (770-488-7100) is recommended.

Patients with known or suspected acute exposures to infectious BW agents are likely to be asymptomatic and require no emergent interventions. Such patients require initiation of appropriate postexposure prophylactic antibiotics and/or vaccinations, depending on the agent involved. Asymptomatic patients acutely exposed to anthrax or plague may be discharged home with antibiotic prescriptions, if adequate follow-up can be arranged through the local public health agency or their private physicians.

Patients exposed to smallpox may require quarantine, which should be coordinated with the assistance of public health and law enforcement agencies. Patients acutely exposed to toxin weapons

might be asymptomatic at presentation but still require admission for a period of observation depending on the agent involved. Botulinum toxin exposure, for example, mandates admission to monitor for development of respiratory failure.

Unless part of a mass-casualty incident, all patients known or suspected to have illness from BW agent exposure should be admitted, with the level of care dependent on clinical severity. Outpatient management of cutaneous anthrax may be considered for patients without systemic toxicity, who can tolerate oral antibiotics, and in whom outpatient follow-up can be assured. Isolation precaution will be necessary for patients with pneumonic plague, smallpox, and many of the VHFs. In mass-casualty situations, admission may need to be more selective and reserved for patients who cannot tolerate outpatient therapy but who are not moribund.

Common Pitfalls

- Lack of familiarity with likely BW agents and the clinical syndromes they produce.
- Failure to appreciate that some BW agents are transmissible and others are not and that isolation requirements will vary.
- Failure to institute appropriate postexposure prophylaxis among patients with plausible exposure scenarios.
- Failure to have a plan with established contacts to hospital, local public health, infectious disease and other experts.

CHAPTER 350 Chemical Warfare Agents

D. Adam Algren and Michael R. Christian

Chemicals have been used to impede, incapacitate, or kill the opposition throughout history. Although international treaties (e.g., 1925 Geneva Protocol, 1997 Chemical Weapons Convention) ban the development, production, stockpiling, and use of chemical weapons, Iraq used both nerve and blistering agents in its war with Iran and against Kurdish civilians in the 1980s. The Russian military used a gas thought to contain a fentanyl derivative and halothane to subdue Chechen rebels in a Moscow theater in 2002 and there is reported use of nerve agents in 2013 against rebels by the Syrian National Army (1).

Of greater concern is that chemical warfare agents (CWAs) may be used by terrorists. CWAs are fairly inexpensive and easy to acquire, synthesize, deploy, and hide. On three occasions, the terrorist group Aum Shinrikyo released nerve agents (sarin and VX) in Japan (2). The Tokyo subway incident in 1995 resulted in 12 deaths and more than 5,000 civilian casualties (2). The 1996 Defense against Weapons of Mass Destruction Act, directed the US Department of Defense to establish preparedness programs of local, state, and federal agencies to respond to chemical and biologic incidents (3) and these became better supported following the September 11, 2001 terrorist attacks.

CWAs can be lethal or nonlethal and fall into one of seven major categories: (a) chemical choking agents, (b) vesicating or blister agents, (c) lacrimating agents, (d) nerve agents, (e) vomiting agents, (f) systemic asphyxiants, and (g) incapacitating agents (Table 350.1)

(4). Lacrimating agents are also used for personal protection and by police for crowd dispersal and incapacitating criminal suspects.

TABLE 350.1
Chemical Warfare Agents

Classification	Military Code	Chemical Name/Common Name
Lethal Agents		
Blood agents	AC	Hydrogen cyanide
	CK	Cyanogen chloride
	SA	Arsenic trihydride/arsine
Choking agents	CL	Chlorine
	CG	Carbonyl chloride/phosgene
	DP	Trichloroethyl chloroformate/diphosgene
Vesicating agents		
Mustards	HD	Bis(2-chloroethyl)sulfide/distilled mustard
Nitrogen mustards	HN-1	2,2-Dichlorotriethylamine
	HN-2	2,2-Dichloro-N-methylethylamine
	HN-3	2,2,2-Trichlorotriethylamine
Arsenicals	MD	Methyldichloroarsine
	PD	Phenyldichloroarsine
	ED	Ethyldichloroarsine
	L	Dichloro(2-chlorovinyl)arsine/lewisite
Oximes	CX	Dichloroform oxime/phosgene oxime
Mixes	HL	None/ML mix (mustard–lewisite mixture)
	HT	None/HT mix (mustard–T mixture)
(Not produced)	Q	4,Bis(methylchloroethyl sulfide)/Q
	T	Bis(2-chloroethyl sulfide)monoxide/T
Nerve agents	GA	Ethyl *N*,*N*-dimethyl phosphoamicocyanidate/tabun
	GB	Isopropyl methyl phosphonofluoridate/sarin
	GD	Pinacolyl methyl phosphonefluoridate/soman
	GF	Cyclohexyl-methyl phosphonofluoridate/cyclosarin
	VR	O-isobutyl S-(2-diethylamino)ethyl methylphosponothioate
	VX	Ethyl S-2-diisopropyl aminoethyl methylphosphonothiolate/VX
Nonlethal Agents		
Vomiting agents	DA	Diphenylchlorarsine
	DC	Diphenylcyanoarsine
	DM	Diphenylaminochloroarsine/adamsite
Lacrimating agents	CA	Bromobenzeneacetonitrile/camite
	CN	2-Chloro-1-phenylethanone/chloroacetophenone
	CNB	None/chloroacetophenone, carbon tetrachloride, benzene mix
	CNC	None/chloroacetophenone chloroform mix
	CNS	None/chloroacetophenone, chloroform, chloropicrin mix
	CR	Dibenz-1,4-oxazepine
	CS	*o*-Chlorobenzlidene malonitrile/CS (tear gas)
	OC	Capsaicin/pepper spray
Incapacitating	BZ	3-Quinuclidinyl benzilate

CWAs can be aerosolized or vaporized and delivered in multiple ways. They may be dispersed from handheld or vehicle-mounted devices, low-flying aircraft, crop dusters, cruise missiles, and artillery. Sarin was dispersed by evaporation from punctured plastic bags left on Tokyo subway cars (2). Although CWAs could be added to water or food supplies, aerosolization is favored by terrorists and military groups as it allows for the greatest exposure with the goal of inflicting the maximum number of casualties (4).

Systemic asphyxiants incorrectly labeled as "blood agents" by the military include the gases cyanogen chloride, hydrogen cyanide (see Chapter 329), and hydrogen sulfide (see Chapter 332), and the hemolytic gas arsine (see Chapter 336) (4). Hydrogen cyanide (prussic acid) and cyanogen chloride are clear liquids with a bitter almond odor that readily volatilize at temperatures $>26^{\circ}$F (1). As warfare agents, their efficacy is limited by physical properties that result in ineffective dispersal (4).

The *choking agents* are pulmonary irritants introduced in World War I and include chlorine, phosgene, and diphosgene (see Chapter 336). Chlorine, a dense, water-soluble, yellow-green gas that smells like concentrated bleach, reacts with tissue water to form hydrochloric acid and oxygen-free radicals, which produce corrosive and cytotoxic effects. Toxicity is proportional to the gas concentration, duration of contact, and water content of exposed mucous membranes.

Phosgene (carbonyl chloride) was probably responsible for more than 80% of all chemical-agent fatalities in World War I (4) and can be formed by decomposition of chlorinated hydrocarbons. It is a colorless gas that is heavier than air. Its propensity to settle into low-lying areas, such as trenches, led to its tactical success. Phosgene smells like freshly mown hay, but odor is not a reliable indicator of exposure. Because of its low water solubility it is only mildly irritating to the eyes and upper respiratory tract and the initial exposure may go unnoticed (4). Phosgene hydrolyzes with terminal bronchial and alveolar mucosal water to produce

hydrochloric acid. This and other toxic by-products of phosgene (e.g., oxygen-free radicals) result in pulmonary edema that can be delayed up to 24 hours. The latency period is shorter with higher concentrations and longer durations of exposure.

Vesicating agents, which cause blistering of exposed surfaces, include mustard gases and organic arsenicals. Sulfur mustard was used in World War I and in the Iran–Iraq war (4). Most injuries were disabling but nonfatal; mortality during World War I was $<2\%$, and rates of 3% to 4% were reported in the Iran–Iraq war (4,5). Street clothing offers no protection, but military protective garments (chemical-resistant suit) can provide up to 6 hours of protection following exposure (6). Low volatility of the liquid results in persistence for several days in temperate climates, thereby restricting enemy use of contaminated equipment and terrain (4).

Sulfur mustard is an oily amber liquid that smells like burning garlic or mustard. Upon tissue contact, it spontaneously forms highly reactive and unstable episulfonium compounds, which irreversibly alkylate nucleic acids and cellular proteins within minutes of exposure (6). This permanently damages DNA and alters or inhibits cell replication, protein synthesis, and enzyme function often leading to cell death. Blisters form after destruction of anchoring filaments in the epidermal–dermal junction (6).

Lewisite, the best known organic arsenical, was developed in 1918 to complement sulfur mustard as a semipersistent blistering agent. Its vapor is about seven times heavier than air and will flow into lower terrain (4). It has low water solubility and persists in the environment for up to 24 hours under temperate conditions. Many countries have large stockpiles of lewisite, but its actual use in combat is not well documented (4).

Lewisite is an amber, oily liquid that smells like geraniums. It is rapidly absorbed after vapor inhalation and, as a result of high lipid solubility, penetrates intact skin within 15 minutes, more rapidly than mustard agents (4). In the dermis, it hydrolyzes to hydrochloric acid and chlorovinylarsenious oxide, the vesicating agent. The organic arsenical moiety binds to the dithiol component of pyruvate dehydrogenase, prevents formation of acetyl coenzyme A from

pyruvate, and produces systemic toxicity similar to other arsenicals (see Chapter 326). Increased capillary permeability and extensive interstitial fluid losses may result in hypovolemia or "lewisite shock" (4).

Nerve agents are similar in structure and function to organophosphorus pesticides (see Chapter 318) but are more potent and typically have a more rapid onset and shorter duration of action. The "G" (German) agents tabun (GA), sarin (GB), and soman (GD) were developed in Germany between 1936 and 1944 (4,7). A fourth, VX, with the "V" standing for "viper," was synthesized in 1952 in England (4,5). Although commonly referred to as gases, these agents are colorless, odorless liquids that under temperate conditions form vapors are heavier than air and concentrate close to the ground (4,7). Lethality correlates directly to the product of vapor concentration and time of exposure (LCt) (4,7). The G agents are moderately volatile, evaporate within several hours, and are environmentally nonpersistent (7,4). VX, an oily liquid, is much less volatile and persists for several weeks after dispersion (4). It is the most potent nerve agent, with an LCt_{50} (vapor concentration–time product necessary to kill 50% of an unprotected population) that is 5, 10, 40, and 500 times more potent than soman, sarin, tabun, and hydrogen cyanide, respectively (4,7). VX also has a slower rate of elimination than G agents and is expected to have a longer duration of action. In addition to inhalational exposures nerve agents can also be absorbed through the skin due to their high lipid solubility. Time of onset and severity are determined by the dose, agent, and skin integrity/location (4,7).

Toxicity of *nerve agents* results primarily from phosphorylation and inactivation of acetylcholinesterase (AChE) at its hydroxy group in its serine active site (see Chapter 318). AChE accumulates at nerve terminals, initially stimulating and then paralyzing cholinergic neurotransmission at both central and peripheral nicotinic and muscarinic receptors. Once inactivated, the phosphorylated AChE enzyme may be permanently inhibited or it may be reactivated by nucleophilic oximes to end the nerve gas

effect. Reactivation is impossible once dealkylation (“aging”) of the phosphorylated cholinesterase occurs. The rate of aging varies among the nerve agents. It occurs within 2 minutes after soman exposure making it difficult to treat, 5 to 8 hours after sarin exposure, and more than 40 hours after tabun or VX exposure (4,7).

Other mechanisms likely contribute to effects on central nervous system (CNS) neurotransmission that result in seizures and CNS neuropathology. This likely explains why some compounds that are neuroprotective do not reactivate AChE and why CNS-active oximes (e.g., pralidoxime) are not more effective than oximes that do not reach the brain.

Vomiting agents are arsenic-based compounds used for riot control (4). They are normally solids that are vaporized by heating and then condense to form aerosols that produce rapid irritation of exposed tissues.

Lacrimating, or riot-control, agents, include *o*-chlorobenzylidenemalonitrile (CS or tear gas), ω-chloroacetophenone (CN or mace), dibenz-1,4-oxazepine (CR), and oleoresin capsaicin (OC or pepper spray). Except for capsaicin, toxicity results from alkylation and inhibition of sulfhydryl-containing enzymes. Generation of bradykinin also contributes to their toxicity. Capsaicin is a lipid-soluble alkaloid that first stimulates release of substance P from nociceptive neurons and then blocks its synthesis and transport. Substance P depolarizes neurons to produce dilatation of blood vessels, stimulation of smooth muscle, and activation of sensory nerve endings that mediate pain. With repeated application, nociceptive fiber response and number are decreased (desensitization).

CN and CS are usually delivered as a vapor or cloud of suspended solid particles (smoke) produced by a thermal grenade. CS is the riot-control agent of choice in the United States. It is about 10 times more potent as a lacrimator than CN but is much less corrosive to tissues (6,7). Newer CS formulations consist of an unheated micropulverized powder that can remain active in the environment for several weeks. OC is used frequently by civilians for personal protection and by law-enforcement personnel for immobilization of

combative subjects. “Pepper mace” can contain CS, oleoresin of capsicum, or both.

Incapacitating agents include stimulants (e.g., amphetamines), depressants (e.g., opioids), psychedelics (e.g., d-lysergic acid diethylamide, LSD), and deliriants (e.g., anticholinergics) (4). Historically, the anticholinergic agent 3-quinuclidinyl benzilate (BZ) was the only incapacitating agent considered feasible for use by the US military (4). BZ is a potent, glycolate, anticholinergic agent that is a crystalline solid under normal atmospheric conditions but most likely dispersed as a vapor or liquid aerosol by military personnel or terrorists (4). Although ultrapotent fentanyl derivatives (alfentanil, carfentanil, remifentanil, and sufentanil) show some promise, these agents have unpredictable effects as a result of high lipid solubilities and large volumes of distribution (1). The unpredictable nature of these agents is evidenced by the tragic end to the October 2002 Moscow hostage crisis in which 127 of 800 hostages died from a fentanyl-halothane gas intended to incapacitate its victims (1).

CLINICAL PRESENTATION

Choking Agents

Clinical symptoms begin within minutes after significant chlorine exposure and include lacrimation, conjunctival irritation, rhinorrhea, cough, sore throat, chest burning, dyspnea, sputum production, nausea, headache, and respiratory failure. Corneal abrasions and cutaneous burns may result from eye and skin exposure, respectively. Following significant chlorine exposures, pulmonary edema develops within 2 to 4 hours and peaks at 12 to 24 hours (4). The chest x-ray may be normal or may show noncardiogenic pulmonary edema. Patients with significant phosgene exposure have a typical latency period of 4 to 6 hours (range, 1 to 24 hours) and then present with dyspnea, chest tightness, cyanosis, hemoptysis, hypotension, and pulmonary edema. Chest x-ray findings of pulmonary edema are rather late and nonspecific, occurring 6 to 8 hours after exposure. Following significant pulmonary agent exposure (e.g., chlorine gas), patients

may subsequently develop reactive airways dysfunction syndrome, a chronic asthma-like condition.

Vesicating Agents

After mustard exposure, there is typically a latency period of 4 to 12 hours before the onset of symptoms. The latency period is shorter with high concentrations and long exposures, with increased ambient temperature and humidity, and in victims previously exposed to or innately susceptible to mustard (4,6). Sites of injury principally involve the skin, eye, and respiratory tract and may follow vapor or liquid exposure. Heavy exposure may lead to systemic effects such as bone marrow depression and sloughing of intestinal mucosa.

Cutaneous injury resulting from mustard exposure ranges from erythema to blisters and skin necrosis. The moist, thinner skin of the neck, axilla, and groin is more severely affected. After of 4 to 12 hours, erythema and edema develop. Vesication typically starts within 24 hours and evolves over several days. Vesicles coalesce into blisters, and skin necrosis occurs over 24 to 72 hours (4). Blister fluid does not contain active mustard and is not toxic (4). Skin denudation occurs over 6 to 9 days, and healing may take 4 to 10 weeks.

The eye is the organ most sensitive to sulfur mustard. Tissue injury occurs rapidly, but symptoms develop gradually over 4 to 8 hours and include eye pain, lacrimation, photophobia, and blurred vision (4,6). Physical findings include blepharospasm, eyelid edema, conjunctival injection and edema, chemosis, anterior chamber cellular infiltrates, and decreased vision. Corneal edema begins within 1 hour after exposure, and the corneal epithelium vesicates and sloughs within 4 to 36 hours (4). Resolution of injury depends on the severity of exposure and typically takes 1 to 2 weeks. About 90% of victims are visually disabled for 10 days with conjunctivitis, photophobia, and corneal swelling. The remaining 10% are severely affected and are at risk for permanent blindness from corneal opacification, scarring, and ulceration (4).

Respiratory epithelial damage occurs several hours after exposure. Victims may develop rhinitis, nasal bleeding, sinus discomfort, hoarseness, sore throat, cough, sputum production, and dyspnea of increasing severity. Hemorrhagic inflammation and erosions of the upper airway mucosa are followed by fibrinous pseudomembrane formation and sloughing of necrotic, ulcerated mucosa. Bronchospasm and partial airway obstruction result. After high-dose exposures, severe bronchitis, secondary bronchopneumonia, and respiratory failure may develop within 24 to 48 hours (4,6). Pulmonary edema is uncommon, as mustard does not typically affect the pulmonary parenchyma. The need for mechanical ventilation is a poor prognostic sign, and the majority of these patients subsequently die from progressive respiratory failure.

Bone marrow and gastrointestinal (GI) mucosal toxicity may occur with high concentration or prolonged exposure. Leukopenia develops within 5 to 7 days, with the white cell nadir occurring 10 days after exposure. Thrombocytopenia and anemia typically follow. The development of hematologic effects from mustard poisoning is a grave prognostic sign (4). Respiratory failure, bone marrow suppression, or superimposed bacterial infection are the most common causes of death from sulfur mustard poisoning (5,6).

The clinical manifestations of lewisite poisoning are similar to those of sulfur mustard, although lewisite causes immediate severe pain on contact with the skin, eyes, and nasal mucosa. Vapor condensing on the skin causes erythema within 30 minutes and blister formation within 2 to 3 hours (4). The eyes are very sensitive to lewisite, and permanent blindness from corneal destruction may result if decontamination is not initiated within 1 minute. Inhalation of lewisite vapor can result in death within 10 minutes from rapid respiratory mucosal sloughing and bleeding, leading to asphyxiation. Pulmonary edema may also develop.

Nerve Agents

Toxicity may occur after inhalation of vapor, skin contact with vapor or liquid, or ingestion. The rate of onset and severity of effects

are determined by the route of exposure and dose (4). At high ambient temperature, skin absorption is rapid and increasing amounts of the agent are volatilized, leading to increased inhalation (4). Small amounts of vapor cause miosis, rhinorrhea, mild dyspnea, cough, and wheezing (4). This can occur within seconds to minutes. Symptoms include eye pain, blurred and dim vision, headache, and dizziness (2). As the dose of vapor increases, nausea and vomiting, increased respiratory difficulty, progressive muscular weakness, and agitation develop. A high vapor concentration causes rapid loss of consciousness, seizures, flaccid paralysis, and respiratory arrest within seconds to minutes. Following sarin vapor exposure in the Tokyo incident, the most common manifestations were miosis (99%), headache (75%), dyspnea (63%), nausea (60%), eye pain (45%), blurred vision (40%), and vomiting (37%) (2). After a mass-casualty incident due to a nerve agent, miosis may serve as a useful marker of exposure. Tachycardia and hypertension were common, but bradycardia and bronchorrhea were not. Electrocardiographic manifestations include supraventricular and ventricular dysrhythmias, ischemic ST–T changes, atrioventricular conduction disturbances, and QTc interval prolongation (7). Seizures may be single and brief or multiple and persistent; status epilepticus will often occur in severely poisoned patients (2,7). Death is primarily a result of depression of the central respiratory drive (4,7). Respirations cease before significant neuromuscular blockade or bronchoconstriction occurs.

Victims of vapor exposure are unlikely to deteriorate once removed from exposure (2). In contrast, those with dermal exposure may subsequently worsen. Skin absorption of a lethal dose may occur within 1 to 2 minutes, yet symptoms are commonly delayed and develop after a latency period of 30 minutes to 18 hours (4,6,7). Skin exposure may produce local sweating and twitching or fasciculations before systemic toxicity (4,7). Conversely, serious effects may also occur abruptly, without antecedent local or mild symptoms after dermal exposure (7). In contrast to vapor exposure, miosis is absent early following skin exposure. Miosis may be

present for weeks after exposure and does not readily respond to systemic treatment (7).

Lacrimating Agents

Within seconds to minutes of exposure, lacrimating agents cause intense eye discomfort, blepharospasm, lacrimation, stinging and burning of the mouth and nose, salivation, rhinorrhea, irritation of the respiratory tract and stomach with coughing and vomiting, and skin irritation leading to burning pain and erythema (4). Because they are miscible in sweat, skin irritation is amplified in areas of increased sweat, such as the axilla, buttocks, and popliteal, antecubital, and inguinal regions. Skin effects increase with concentrated liquid spray or aerosol exposures, in warm, moist environments, and in those with pre-existing skin conditions. Toxic effects following exposure to tear agents typically resolve within 20 to 30 minutes (4). High-concentration, enclosed-space exposures, however, may result in significant respiratory effects that include acute laryngotracheobronchitis, pulmonary edema, and death. Pulmonary edema can be delayed 4 to 8 hours; peak effects should be evident by 12 hours.

Prolonged or repeated exposures to lacrimating agents may produce malaise, skin blistering, chest tightness, coughing, wheezing, hemoptysis, shortness of breath, and a feeling of suffocation. Reactive airways dysfunction (RADS) and allergic contact dermatitis have been described in sensitized individuals. A severe dermatitis, labeled “Hunan hand syndrome,” has been described after prolonged skin exposure to capsaicin containing chili peppers.

Incapacitating Agents

Manifestations of BZ and fentanyl derivative poisoning are described in detail in Chapter 344 and Chapter 305, respectively. BZ poisoning may occur after inhalation of vapor or liquid aerosol, intravenous or intramuscular injection, or, to a small degree, skin contact with liquid. Following exposure by all routes (except skin), the onset of

effects takes 1 hour, peaks at 8 hours, and gradually subsides over 24 to 72 hours (4). Effects may be delayed up to 24 hours after dermal exposure. Doubling the dose produces incapacitation within 1 hour and prolongs recovery an additional 48 hours. Wide variability in the onset, severity, and duration of effects should occur after BZ deployment by aerosol or vapor (4). The rate of onset and duration of clinical effects after inhalation of aerosolized fentanyl derivatives has not been fully described (1). The gas mixture utilized in the Moscow hostage crisis produced effects within 15 minutes of exposure; toxicity lasted days in some survivors (1).

DIFFERENTIAL DIAGNOSIS

Deliberate release of chemicals by terrorists is likely to involve substances that cannot be immediately identified. Thus, the most likely diagnosis is likely to be made by history, physical examination, and initial diagnostic testing (8,9). Diagnosis is also strongly suggested by the complete reversal of toxic effects following empiric antidotal therapy (1,2,10).

CWA poisoning should be suspected when a group of patients present with the abrupt onset of a similar constellation of signs or symptoms, particularly if they involve the exposed mucosal or skin surfaces, the respiratory tract, or sudden systemic effects (8,10). Following a chemical attack, clinical effects will occur within minutes to hours, and large numbers of symptomatic patients from the same location will present to medical facilities within a short period of time (3,8,10). There may be an associated explosion and/or reported vapor cloud with or without a characteristic odor. In contrast, clinical effects after a biologic agent attack are delayed as a result of the incubation period of the illness and patients will present insidiously, often with nonspecific signs and symptoms. It will be difficult to identify the release site of the weapon, and the geographic distribution of patients may be wide by the time symptomatic disease develops (see Chapter 349) (8,10).

Irritant or corrosive gas inhalation, hydrocarbon aspiration, and vesicating agent and high-dose lacrimating agent exposures may produce pulmonary signs and symptoms similar to those caused by choking agents. Exacerbations of asthma, chronic obstructive pulmonary disease, and allergic or infectious pneumonitis may present similarly. The vesiculobullous skin lesions that result from vesicating agents are most pronounced on exposed skin but may mimic those resulting from Stevens–Johnson syndrome, toxic epidermal necrolysis, pemphigus vulgaris, bullous pemphigoid, scalded skin syndrome, thermal and chemical burns, and hypersensitivity reactions. Nerve-agent poisoning is nearly identical to organophosphate and carbamate pesticide poisoning. Other agents and conditions that can produce similar clinical effects are botulism; nicotine; cholinergic drugs such as bethanechol, carbachol, edrophonium, methacholine, neostigmine, pilocarpine, physostigmine, pyridostigmine, and succinylcholine; and pyrethroids.

Nerve-agent, cyanide, or fentanyl-derivative exposure should be suspected if victims become comatose within minutes of exposure (4,8,10). Although the presence of coma, miosis, and respiratory depression is likely following exposure to both opioid and nerve agents, the additional presence of a seizure, fasciculations, and/or cholinergic findings strongly suggest intoxication with a nerve agent (10). Although seizures may be present following exposure to both cyanide and nerve agents, the presence of intractable hypotension and acidemia despite adequate oxygenation suggests severe cyanide toxicity (4,8,10). BZ will produce effects identical to other anticholinergic agents (4). In the absence of history, unintentional atropine poisoning following use of a nerve-agent autoinjector cannot be differentiated from BZ toxicity. Lacrimating agents cause effects similar to those of irritant gas and lewisite exposure. Anxiety and hysterical reactions must also be considered in the differential diagnosis of patients exposed to warfare agents.

ED EVALUATION

Despite the probable confusion and panic and conflicting reports, an attempt should be made to document the amount, time, nature, and duration of exposure. The color and odor of the toxic agent may provide clues to its identity. The time of onset, nature, progression, severity of symptoms, and prehospital treatment should be noted.

Physical examination should first focus on vital signs and an assessment of neuromuscular and cardiopulmonary function and then on the eyes, skin, and GI tract. Following stabilization, patients with eye symptoms should have fluorescein and eventual slit-lamp examinations. If signs and symptoms of cyanide, choking, vesicating, or lacrimating agent toxicity are present, ancillary studies should include a chest radiograph, electrocardiogram (ECG), and arterial blood gas analysis, depending on the severity of symptoms. Additional laboratory evaluation after exposure to cyanide or a vesicating agent should include baseline complete blood count and serum electrolyte, blood urea nitrogen, creatinine, and glucose levels. Measurements of whole blood or plasma cyanide confirm cyanide poisoning but are rarely readily available. High blood lactate concentrations, a large anion gap metabolic acidosis, and high venous blood oxygen content suggest cyanide poisoning.

Patients with signs and symptoms of nerve agent toxicity should have a chest radiograph, ECG, arterial blood gas analysis, routine admission laboratory studies, and measurement of peak expiratory flow rate and plasma or red blood cell cholinesterase activity (see Chapter 318). Cholinesterase activity, however, will not be available in time to be useful in making treatment decisions, and it does not always correlate with the severity of disease (4,10). In the Tokyo sarin attack, 27% of patients with clinical manifestations of moderate poisoning had plasma cholinesterase levels in the normal range (2).

Routine toxicology testing will not identify CWAs. The diagnosis of CWA poisoning is confirmed by detecting chemical agents and their degradation products or cellular macromolecule adducts in environmental or body fluid samples. Formal identification of CWAs is likely to be performed at state and federal law enforcement laboratories with the assistance of federal public health authorities

(Centers for Disease Control laboratory). Rapid-detection kits are used by law enforcement in the prehospital setting to quickly identify the agent involved.

One of the objectives during the evaluation is to separate the truly exposed from the worried-well or anxious patients to focus the resources on patients who are in the greatest need.

KEY TESTING

- Obtain a chest x-ray in those with respiratory symptoms following exposure to choking, vesicating, nerve, or lacrimating agents.
- Obtain an arterial blood gas, serum chemistries, lactate level, and whole blood or serum cyanide level in those with findings suggestive of cyanide poisoning.
- Consider obtaining RBC and plasma cholinesterase levels in those with symptoms suggestive of nerve agent exposure.

ED MANAGEMENT

In the event of a chemical weapon attack, emergency field personnel will be responsible for performing on-scene triage, decontamination, and initial treatment prior to patient transport. Appropriate scene and decontamination control zones should be established. Emergency field personnel should wear appropriate personal protective equipment (PPE). If the hazardous substance is unknown, this consists of an encapsulated, vapor-impermeable, and chemical-resistant suit; chemical-resistant gloves and boots; and a positive-pressure, self-contained breathing apparatus (level A PPE) (3,5,8,10). The importance of first-responder personal protection was illustrated in the Matsumoto and Tokyo sarin gas attacks in which 10% to 35% of rescuers developed mild toxicity (2). In each incident, patients were not decontaminated, and rescuers wore standard work clothing without respiratory protection. Mouth-to-mouth rescue breathing should be avoided as 10% of inhaled nerve agents are expired and could result in rescuer toxicity. Hospitals should be prepared to activate their disaster plans and be able to

decontaminate those are inadequately decontaminated or those that arrive by self-transport (3,10). Details of disaster planning and management are discussed in Chapter 378. ED personnel treating a patient exposed to an unknown chemical agent should wear a chemical-resistant suit, gloves, and boots and an external self-contained breathing apparatus (SCBA) or positive-pressure supplied air respirator (level B PPE) until the threat of secondary exposure is cleared (3,5,10). Removal of dry substances along with removal of clothing eliminates up to 90% of the hazard and is the most effective step in decontamination (7–10). Clothing should be discarded in impervious plastic bags, particularly leather items (e.g., shoes, watchbands), which can absorb chemicals and result in reexposure. Dermal decontamination involves irrigation with tepid water, followed by 0.5% hypochlorite solution (household bleach diluted 1:10 with water) or alkaline soap, and then repeated, thorough water rinsing (3,4,10). The wastewater should be collected and isolated, if possible. If exposed, the eyes should be irrigated with copious amounts of water or saline. Rapid dermal decontamination is critical following exposure to the liquid or aerosolized formulations but less important following isolated vapor exposure (3).

After decontamination, management of victims includes establishing an airway and supporting breathing and circulation. Ideally, all patients should have oxygen provided and receive continuous cardiac and oxygen saturation monitoring, but in mass-casualty situations priority must be given to the most severely affected patients.

Other workup is dictated by clinical severity including management of traumatic injuries. For inhalation exposure initial treatment includes administration of 100% humidified oxygen, bronchodilators, and assisted ventilation, as necessary.

Choking Agents

Treatment of choking agent poisoning consists of providing humidified oxygen, β-adrenergic agonist bronchodilators,

ventilatory support, intravenous crystalloids for hypotension (4). Nebulized 2% sodium bicarbonate may provide symptomatic relief following acute chlorine gas exposure (8,10). Although frequently recommended for chlorine and phosgene exposure, corticosteroids have no proven benefit.

Vesicating Agents

Because of rapid and irreversible binding to tissues, immediate decontamination is the best form of treatment for mustard agent exposure (4,6,10). Water alone is ineffective, as mustard is relatively water-insoluble. Dilute bleach is recommended as it produces "free" chlorine, which inactivates the mustard compound. Copious water or saline irrigation is the favored method for ocular decontamination. Exposure to tissue or vesicle fluid will not produce secondary injury to healthcare personnel (5).

Treatment is otherwise supportive. Blisters and necrotic skin should be debrided. Skin burns should be treated with topical antibiotics. Ocular injury requires urgent ophthalmologic consultation. Treatment may include topical anesthetics, antibiotic ointment to prevent infection, and mydriatic or cycloplegic medication to prevent adhesions between iris and cornea (4,6,10). Respiratory care is the same as for choking agents.

Potential antidotes for sulfur mustard poisoning include mustard scavengers (glutathione, N-acetylcysteine, thiosulfate), antioxidants (vitamin E), NAD^+-level stabilizers (niacin and nicotinamide), anti-inflammatory drugs (corticosteroids, indomethacin), and nitric oxide synthase inhibitors (L-nitroarginine methyl ester) (4). Bone-marrow suppression may respond to granulocyte-colony–stimulating factor.

Treatment of lewisite exposure involves washing the skin with water, soap, solutions of dilute chlorine bleach (0.5%), or baking soda (sodium bicarbonate) (4). Neither scrubbing nor hot water is appropriate, because both enhance lewisite absorption and toxicity. Blisters, shown to contain arsenic, should be opened and drained of fluid. Other treatment is identical to that of thermal burns.

Historically, systemic lewisite poisoning has been treated by intramuscular British antilewisite (BAL, 2,3-dimercapto-propanol, or dimercaprol), an arsenic chelator antidote, along with supportive care (see Chapter 326). BAL has also been used topically as a 5% ointment for skin lesions and as a 5% to 10% oil solution for ocular symptoms. Newer, less toxic dithiol analogs of BAL, meso-dimercaptosuccinic acid (DMSA) or 2,3-dimercapto-1-propan-sulfonic acid (DMPS) can be administered and have equal efficacy (see Chapters 326 and 334).

Nerve Agents

Intubation, mechanical ventilation, and the use of muscarinic antagonists (e.g., atropine), oximes (e.g., pralidoxime), and benzodiazepines (e.g., diazepam) may be necessary. If endotracheal intubation is necessary, a nondepolarizing neuromuscular blocker such as rocuronium (1.0 mg/kg IV) is recommended to avoid prolonged paralysis from succinylcholine. Antidotal therapy is discussed in Chapter 318. Initially, atropine should be administered intravenously at a dose of 2 mg every 3 to 5 minutes (0.02 to 0.05 mg/kg in children) until respiratory secretions clear, bronchospasm resolves, and ventilation is normal (5,7,9). Heart rate and pupil size are poor endpoints for adequate atropinization (2,4,7,9). Cumulative atropine doses of 10 to 20 mg are usually adequate over the first 2 to 3 hours, with little or no therapy required thereafter (2,4). This differs from organophosphate pesticide poisoning, which may require significantly greater amounts of atropine and a longer duration of therapy. In the Tokyo sarin attacks, only 19% of poisoned patients required more than 2 mg of atropine; severely poisoned patients required 1.5 to 15 mg of atropine (mean, 6 mg) (2). Topical mydriatic cycloplegic eye drops such as tropicamide (Mydriacyl) may be used for intractable eye pain as a result of ciliary spasm. No treatment is needed for miosis as an isolated ocular finding.

Oxime therapy is recommended for all cases of nerve-agent poisoning. Because unlike with insecticides, nerve agents age

extremely rapidly, pralidoxime must be given as soon as possible after exposure to be effective. Initially, 1 to 2 g of pralidoxime should be administered as an intravenous bolus over 10 minutes (20 to 50 mg/kg in children), followed by a continuous infusion of 500 mg/hr (10 to 20 mg/kg/hr in children) (5,7,10). Side effects of pralidoxime include hypertension and tachycardia. Pralidoxime is given until signs and symptoms of intoxication have resolved (7). In the Tokyo sarin attacks, severely poisoned patients required 1 to 36 g pralidoxime (mean, 11 g) (2). Conventional oximes (pralidoxime preparations, obidoxime, trimedoxime) are not clinically useful against soman. Newer H-series (Hagedorn) oximes are superior in their ability to reactivate unaged soman-inhibited AChE. They also have direct antimuscarinic and antinicotinic (ganglia-blocking and nondepolarizing neuromuscular-blocking) actions but do not protect from nerve agent–induced seizures (4). HI-6, a bisquaternary pyridinum oxide, is currently the most promising AChE reactivator for the treatment of nerve-agent poisoning; it is effective against all nerve agents and does not result in significant side effects in human studies (4,10). Currently, other oximes are not commonly available in the United States.

Pretreating those at risk with a reversible AChE inhibitor, such as the carbamate pyridostigmine (Mestinon), is also effective against soman, in which enzyme aging is rapid and pralidoxime alone is unlikely to be effective (4). The intent is to carbamylate or bind 20% to 40% of AChE and limit subsequent nerve-agent binding. Carbamylated cholinesterase then spontaneously reactivates or is regenerated with oxime therapy, leaving the victim with enough AChE to function normally. Pyridostigmine pretreatment does not protect against sarin and VX, in which aging is slower and pralidoxime is effective. During the Persian Gulf War, US soldiers were given pyridostigmine bromide in blister packs containing 21 30-mg tablets (4,7). Pyridostigmine was taken orally every 8 hours without causing impaired performance. Side effects were minimal, but they can mimic mild nerve gas poisoning.

Seizure control can protect against sudden death and brain injury (1,4,10). Seizures should be aggressively treated with high-dose

benzodiazepines, such as intravenous diazepam 10 mg (0.2 to 0.4 mg/kg) or midazolam (Versed) (0.1 to 0.3 mg/kg), in addition to standard therapy with an antimuscarinic and oxime agents (7,9,10). Both antimuscarinic agents and benzodiazepines are effective in treating nerve-agent seizures in experimental animals. Trihexyphenidyl (Artane) and midazolam are the most potent and rapidly acting agents. Diazepam should be administered to all severely exposed victims (4).

Lacrimating Agents

Treatment of lacrimating agent exposure is frequently unnecessary because effects resolve quickly, even without irrigation. Symptomatic patients may require supportive care and decontamination with soap and water. Contact dermatitis may respond to topical corticosteroids and antipruritics. Tearing usually irrigates the eyes adequately, but topical anesthetics and saline irrigation may be helpful. Chemical conjunctivitis may benefit from symptomatic treatment with topical vasoconstrictors (see Chapter 56). Corneal injuries are treated with cycloplegics, topical antibiotics, and ophthalmologic follow-up (see Chapter 57). Patients exposed to high concentrations of aerosols, as in enclosed spaces or near exploding tear-gas canisters, should be observed for 12 to 24 hours because of delayed pulmonary effects (4). Treatment of pulmonary toxicity consists of humidified oxygen, bronchodilators, and assisted ventilation, as needed.

Incapacitating Agents

Treatment of incapacitating-agent toxicity includes supportive care and the administration of antidotes. Standard doses of physostigmine (1 to 2 mg or 0.02 mg/kg IV) are usually effective in reversing the anticholinergic effects of BZ (see Chapter 344) (4,10). For unclear reasons, however, physostigmine is ineffective if administered during the first 4 to 6 hours after the onset of clinical effects (4). The treatment of fentanyl-derivative poisoning is similar to that for other opioids (see Chapter 305). Because these agents

bind with high affinity to opiate receptors, large doses of naloxone may be required for complete reversal of toxic effects. As a result of high lipophilicity, fentanyl derivatives redistribute from tissue stores to the CNS and are more likely to produce recurrent CNS depression (1). Based on animal studies, naloxone antagonist redosing is likely to be necessary for a period of 2 to 24 hours (1).

CRITICAL INTERVENTIONS

- Decontaminate victims of CWA exposure by removing, bagging, and discarding all clothing, and washing the skin with copious amounts of soap and water.
- Wear level B PPE (e.g., chemical-resistant suit, gloves, boots, SCBA) when the CWA is unknown and protect caregivers from exposure.
- Notify local and federal law-enforcement authorities along with local or state health departments when CWA poisoning is suspected.
- Activate the hospital disaster plan and establish a decontamination area outside the ED for mass-casualty incidents.
- Administer oxygen, bronchodilators, and artificial ventilation to patients with respiratory symptoms following choking, vesicating, and lacrimating agent exposure.
- Administer antidotal therapy to victims with cyanide, nerve agent, anticholinergic, and opioid poisoning and titrate to clinical improvement.

DISPOSITION

Asymptomatic patients with choking agent exposure should be observed and monitored for at least 6 hours. Mild to moderately symptomatic patients may be discharged safely after several hours of observation if symptoms have improved or resolved with treatment. Victims of lacrimating agents may be treated and released if there is no significant pulmonary toxicity. Patients with phosgene exposures should be admitted and closely observed because of phosgene's varying latency period and high potential

morbidity. Asymptomatic patients with vesicating agent exposure should be admitted and monitored for 12 to 24 hours. Following exposure to nerve agent vapor, patients with signs and symptoms confined to the eyes may be discharged safely after a short period of observation (2). Those with skin exposure to nerve agents (liquid or aerosolized droplets) should be observed for 24 hours. All patients with systemic symptoms, pulmonary toxicity, and severe or extensive dermal injury should be hospitalized. Patients with corneal or skin burns should have follow-up with an ophthalmologist or plastic surgeon. As a result of the long duration and recrudescent nature of clinical effects from incapacitating agents, all symptomatic victims should be observed for a minimum of 24 hours. The appropriate level of care will depend on clinical severity.

ACKNOWLEDGMENTS

The authors acknowledge the contributions of Michael Joseph Burns and Christopher H. Linden to previous editions of this chapter.

Common Pitfalls

- Failure to protect rescuers and medical personnel from secondary contamination.
- Failure to decontaminate victims of chemical agent exposure in a timely fashion.
- Failure to appreciate that effects can be delayed and progressive and to observe asymptomatic victims for appropriate periods of time.
- Failure to administer antidotes in a timely manner.

CHAPTER 351 Drug Withdrawal

Lewis Nelson

Withdrawal syndromes, which include discrete physiologic and psychological effects, occur following the discontinuation or dose reduction of certain drugs and medications. Anticipating and recognizing the early signs of withdrawal allow for timely treatment and may help prevent the development of serious withdrawal manifestations.

Ethanol withdrawal is a common, potentially life-threatening syndrome (see Chapter 282), and is similar to that occurring after the cessation or dose reduction of sedative-hypnotics such as benzodiazepines, barbiturates, and chloral hydrate, as well as γ-hydroxybutyrate (GHB) and its congeners (e.g., 1,4-butanediol), and baclofen. All of these drugs enhance the activity of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) at the $GABA_A$/benzodiazepine receptor/chloride–channel complex and induce long-standing adaptations in receptor function.

Withdrawal symptoms associated with opioids are common, although generally not life-threatening, and have grown increasingly important during the decade-long epidemic of prescription opioid misuse. Antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs), and cocaine are associated with discontinuation syndromes that are likened to withdrawal, but are less severe. Somatic and psychological symptoms predominate.

Physical dependence is a prerequisite for the development of a withdrawal syndrome, and is generally accompanied by tolerance. The dose of the drug, its duration of action, frequency of administration, and duration of abuse all contribute to the

development of dependence and are related to the severity of withdrawal. More severe withdrawal phenomena may be associated with a longer period of abuse or a history of previous withdrawal episodes. Sporadic use of a drug does not generally induce the receptor adaptations required for the development of dependence, and therefore withdrawal. For example, use of GHB recreationally (e.g., on weekends) does not result in dependence and withdrawal does not occur, whereas it does follow cessation in frequent, several-times-daily users, such as body-builders. Similarly, the withdrawal associated with heroin use is typically less intense than that associated with methadone since the later is long acting and blood concentrations remain elevated around-the-clock. Complete abstinence and a serum drug level of zero are not required, nor is abuse (i.e., use simply for pleasurable central nervous system [CNS] effects). Physiologic dependence does not require excessive doses, and it may occur after prolonged treatment with therapeutic doses for appropriate indications.

Withdrawal from sedative-hypnotics is characterized by intense sympathetic stimulation. The underlying mechanism is not fully elucidated, but it occurs when compensatory CNS mechanisms that counteract the depressant effects of sedative-hypnotics are activated. Such mechanisms involve changes in GABA and glutamate receptor activity, including down-regulation of the GABA receptor complex and upregulation of the *N*-methyl-D-aspartate (NMDA) glutamate receptors. Benzodiazepine withdrawal results in excitatory effects because there is less baseline GABA inhibition and enhanced neuronal activity through overactive NMDA receptors.

Withdrawal from opioids may also involve an increase in sympathetic discharge, but by a different mechanism. Decreased opioid receptor stimulation increases catecholamine release in the locus ceruleus of the CNS. The severe catecholamine surges seen with sedative–hypnotic withdrawal are not observed during typical opioid withdrawal.

CLINICAL PRESENTATION

The clinical presentation of drug withdrawal varies significantly among patients. Although this may relate to variations in the degree of drug use and reporting, there are also individual factors that underlie the severity of withdrawal. Some patients develop significant withdrawal following cessation of exposure, while others with similar use patterns develop minimal effects. Some patients may present with complications of drug abuse, such as pneumonia, endocarditis, and skin abscess, or an unrelated problem, such as a myocardial infarction or motor vehicle accident, and develop withdrawal symptoms while in the emergency department (ED) or after admission. Others present to the ED due to unintended abstinence or because they desire detoxification.

Sedative-hypnotic withdrawal may be indistinguishable from ethanol withdrawal except for differences in the time course (Table 351.1). Because many benzodiazepines have a long elimination half-life and active metabolites, withdrawal manifestations may be delayed after cessation of drug use. Lorazepam withdrawal may begin within 2 days of the last dose, whereas diazepam withdrawal may require a week or more before the onset of symptoms.

TABLE 351.1
Withdrawal Syndromes Commonly Seen in the ED

Type of Withdrawal	Onset after Use Ends
Ethanol	6–8 hrs
Sedative–hypnotic (e.g., benzodiazepines, barbiturates)	3–7 d (for long-acting drugs)
GHB	Hours
Baclofen	12–72 hrs
Opioids	4–8 hrs (heroin); 36–72 hrs (methadone)
Cocaine	Within hours after binge
Antidepressants	2–5 d

The clinical presentation of sedative-hypnotic withdrawal varies in intensity and duration. Mild withdrawal symptoms include anxiety, apprehension, irritability, dysphoria, and insomnia (1). Other symptoms may include anorexia, nausea, and vomiting. Mild

autonomic and CNS hyperactivity is characterized by tachycardia, hypertension, irritability, and hyperreflexia. Unlike patients with severe withdrawal, patients with mild withdrawal have a clear mental status. Most patients with mild withdrawal recover uneventfully after a few days, but some may develop more serious withdrawal manifestations.

Hallucinations, delusions, myoclonus, seizures, and agitation may appear in patients with more severe withdrawal. Tachycardia, hypertension, tachypnea, hyperthermia, diaphoresis, and mydriasis may develop, as may tachyarrhythmias. At times, a new-onset seizure heralds the onset of sedative-hypnotic withdrawal. These patients may or may not have tremulousness and other sympathetic hyperactivity before seizure activity begins. Seizures tend to be generalized and tonic-clonic. Severe withdrawal, including seizures, may occur after the administration of flumazenil to patients chronically taking benzodiazepines. Withdrawal from long-acting benzodiazepines may persist for 3 weeks.

Withdrawal from GHB, or its congeners γ-butyrolactone (GBL) or 1,4-butanediol, may also produce severe withdrawal (2). Withdrawal from these agents is frequently seen in body-builders, who ingest GHB multiple times per day as opposed to sporadic recreational users. Autonomic and CNS abnormalities are the most common effects and may include anxiety and tremor. More severe GHB withdrawal is characterized by severe agitation, tachycardia, hypertension, insomnia, auditory and visual hallucinations, and delirium. The onset of symptoms may appear as early as 1 to 6 hours after the last dose, and the symptoms may persist for as long as 5 to 15 days. Few deaths from GHB withdrawal have been reported (also see Chapter 309).

The withdrawal syndrome from oral or intrathecal baclofen generally starts 12 to 72 hours after discontinuation. Typical findings include sleeplessness, confusion, agitation, hallucinations, delusions, hyperthermia, and hypertonia. Interestingly, seizures may occur in the setting of either baclofen toxicity or withdrawal (3). In some cases, there is profound muscle rigidity resembling neuroleptic malignant syndrome or malignant hyperthermia.

Mild opioid withdrawal includes lacrimation, rhinorrhea, yawning, diaphoresis, anxiety, restlessness, and dysphoria. Piloerection is particularly characteristic. The patient may exhibit mild elevations in pulse, blood pressure, and respiratory rate, but these changes are usually not significant. More severe opioid withdrawal is characterized by vomiting, diarrhea, abdominal pain, and dehydration. Severe agitation, seizures (except in neonatal withdrawal), mental status changes, and dramatic vital sign abnormalities do not typically occur with opioid withdrawal due to abstinence but do occur with opioid withdrawal precipitated by naloxone.

The severity and time course of the opioid withdrawal syndrome depends on the pharmacokinetics of the opioid. Withdrawal from shorter-acting agents (e.g., heroin) usually begins within 4 to 8 hours after the last dose, peaking by 36 to 72 hours while that from longer-acting agents (e.g., methadone) typically occurs 36 to 72 hours after the last dose and may persist for up to 2 weeks. Withdrawal from long-acting opioids tends to be more severe than that from shorter-acting agents.

The sudden onset of opioid withdrawal may occur after an opioid antagonist such as naloxone is given to an opioid-dependent patient (4) and may be severe. As a result of naloxone's short half-life, withdrawal symptoms do not usually persist beyond 40 to 60 minutes. Treatment with additional opioid to reverse these short-lived effects is not indicated. Opioid withdrawal from the long-acting opioid antagonist naltrexone may result in a markedly prolonged withdrawal period lasting up to 24 hours and treatment is difficult. A cautious attempt to overcome the receptor blockade with an opioid is possible, though many simply provide supportive care including antiemetics and benzodiazepines. Giving opioids without full agonist properties, such as buprenorphine (Suboxone; a partial agonist), to a stable opioid-dependent patient may also precipitate withdrawal symptoms. Interestingly, buprenorphine can be used to quell existing or extant opioid withdrawal due to the same pharmacologic properties.

Antidepressant withdrawal/discontinuation may result in anxiety, insomnia, lethargy, nausea, vomiting, headache, imbalance, sensory abnormalities, and possibly aggressive and impulsive behavior. In most cases, these symptoms are mild and transient. Withdrawal from cocaine may result in lethargy, dysphoria, and depression (5).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a patient with a withdrawal syndrome is broad and includes many other serious conditions that may require different therapy (Table 351.2). Because drug-dependent patients are particularly prone to develop many of these conditions, careful exclusion of other etiologies is critically important. Examination may help to distinguish an anticholinergic toxidrome (dry skin, decreased bowel sounds, urinary retention, mydriasis, tachycardia) from a sympathomimetic toxidrome (moist skin, normal bowel sounds, no urinary retention, mydriasis, tachycardia).

TABLE 351.2
Differential Diagnosis of Major Withdrawal Symptoms

Tremor	Seizures	Hallucinations	Delirium
Withdrawal	**Withdrawal**	**Withdrawal**	**Withdrawal**

	Degenerative disease		

LSD, lysergic acid diethylamide; CNS, central nervous system.

Sedative-hypnotic withdrawal may be particularly difficult to distinguish from an underlying anxiety disorder. Differentiating withdrawal seizures from other types of seizures may also be difficult particularly without an accurate history. Other common causes include pre-existing idiopathic epilepsy, posttraumatic epilepsy, and

other complications of drug abuse (e.g., hypoglycemia, hypomagnesemia, hyponatremia, head trauma). Poor anticonvulsant compliance with underlying seizure disorders may add to the diagnostic confusion. In the setting of baclofen use, a seizure could result from either overdose or withdrawal.

Opioid withdrawal must be distinguished from ethanol and other sedative-hypnotic withdrawal because of the significant differences in therapy. Clinical findings of significant sedative-hypnotic withdrawal, such as confusion, agitation, and seizures, are not generally seen with opioid withdrawal; opioid withdrawal symptoms such as piloerection, yawning, lacrimation, and rhinorrhea are not seen with ethanol and sedative-hypnotic withdrawal. Some patients, however, may be withdrawing from both substances. Gastrointestinal (GI) manifestations of opioid withdrawal must be differentiated from abdominal pathology and gastroenteritis.

ED EVALUATION

Patients presenting with drug withdrawal require a comprehensive assessment. Patients initially should have cardiac monitoring and a fingerstick glucose and oxygen saturation analysis. The physician should obtain a complete history of substance abuse, previous withdrawal episodes, and all current and former medications. If possible, family, friends, and prehospital personnel can be interviewed to gain additional information.

Physical examination should focus on vital signs, including rectal temperature; cardiovascular, neurologic, and pulmonary systems; the skin; the abdomen; and the eyes. Close attention should be directed to any stigmata of chronic liver disease or evidence of intravenous (IV) drug use. There should be assessment for obvious and occult traumatic injury and complications of drug abuse, such as pneumonia, skin abscesses, bacterial endocarditis, acquired immunodeficiency syndrome, pancreatitis, liver disease, and GI bleeding (see Chapter 308).

Laboratory studies that may prove helpful include a complete blood count; electrolytes, glucose, blood urea nitrogen, and creatinine levels; liver function tests; lipase; coagulation profile; and

ethanol level. A urine drug screen may be positive or negative for the offending agent, but can also be misleading. For example, rapid urine drug screens may not detect synthetic or semisynthetic opioids such as methadone or oxycodone, respectively. In patients with significant agitation, a creatine phosphokinase determination may detect rhabdomyolysis.

An elevated temperature may require a sepsis workup, including urine and blood cultures, chest radiograph, and, often, a lumbar puncture. Obtaining a head computed tomography (CT) scan before lumbar puncture is suggested in patients presenting with either focal neurologic deficits or high risk for intracranial hemorrhage. Patients with a first-time seizure in the setting of withdrawal should be evaluated in the same manner as any other patient with a new seizure. Subsequent withdrawal seizures do not necessarily require extensive reevaluation.

KEY TESTING

- Screening laboratory testing is of limited value in diagnosis but important for identifying precipitating causes or comorbid conditions. This includes a complete blood count; electrolytes, glucose, blood urea nitrogen, and creatinine levels; liver function tests; lipase; coagulation profile; and ethanol level.
- Head CT may be useful in differentiating the etiology of other causes of altered mental status or seizure.
- Urine drug testing for abused substances is difficult to interpret given the high prevalence of concomitant use of substances unrelated to the clinical presentation and the limitations of the assay for detecting certain abused drugs.

ED MANAGEMENT

Drug withdrawal syndromes, particularly sedative-hypnotic withdrawal, must be recognized and treated in a timely fashion. A successful treatment strategy must address several basic goals: (1) alleviating symptoms, (2) preventing progression, (3) avoiding complications, and (4) recognizing and treating coexisting medical

problems. Planning for long-term rehabilitation and drug independence is usually better done as part of inpatient management.

Initial treatment should be directed at readily correctable causes of altered mental status. Oxygen should be given if the oxygen saturation is low, and an IV line should be established. Glucose and thiamine should be administered if there is evidence of hypoglycemia and malnutrition respectively. Volume resuscitation is often necessary, particularly in patients with severe withdrawal manifestations and dehydration.

Significantly agitated patients may initially need to be physically restrained to prevent injury, establish IV access, and facilitate sedation. Soft restraints should be used but prolonged use of restraints is discouraged, because continued struggling against them may lead to rhabdomyolysis, hyperthermia, and metabolic acidosis. Once IV access is obtained and chemical sedation has achieved behavioral control, physical restraints should be discontinued.

Achieving adequate sedation is the cornerstone of successful treatment of sedative-hypnotic withdrawal. It may prevent progression to agitated delirium with its attendant complications. Reinstitution of therapy with the withdrawn drug or a cross-tolerant one is required for proper sedation. Many agents have been used over the years, but benzodiazepines have proven to be the most effective. Compared with other sedative-hypnotic agents such as barbiturates, benzodiazepines are more easily titrated and produce less respiratory depression and cardiovascular effects (6).

Diazepam (Valium, oral and IV), chlordiazepoxide (Librium, oral only), midazolam (Versed, IV only), and lorazepam (Ativan, oral and IV) are the most commonly used agents for ethanol withdrawal and can also be used for sedative-hypnotic withdrawal. These agents are eliminated over several days and are preferred over benzodiazepines with shorter half-lives. Compared with short-acting agents, long-acting agents may be more effective in preventing withdrawal seizures and contribute to smoother withdrawal with fewer rebound effects. Active metabolites of diazepam and chlordiazepoxide prolong their therapeutic effect. In elderly patients and those with hepatic

dysfunction, lorazepam, which has no active metabolites, may be preferred. In other cases, lorazepam does not appear to offer any distinct advantage over diazepam or chlordiazepoxide.

IV dosing is preferred in most cases of sedative-hypnotic withdrawal. Agitation may preclude oral administration, and GI dysfunction may impair drug absorption. IV therapy can be readily titrated. Intramuscular (IM) lorazepam or midazolam may be useful in the agitated patient before IV access is established but IM diazepam absorption is erratic and should be avoided.

The dose of benzodiazepines required to achieve proper sedation must be individualized and varies considerably, depending on the patient's tolerance to the drug. Symptom-triggered therapy is preferred to fixed-schedule therapy. Frequent IV boluses should be given until the patient has achieved a calm state. Diazepam, 5 to 20 mg IV, can be given every 5 to 15 minutes until the patient is sedate but arousable. For ethanol withdrawal, chloridazepoxide, 50 mg PO titrated hourly, is a typical oral dose. Usually, sedation is obtained before respiratory depression develops, but close airway observation is always required.

Failure to obtain immediate sedation need not prompt switching to an alternative agent. Mixing different drugs or different routes of administration may increase the risk of adverse effects, particularly respiratory depression. However, if a patient does not respond completely to the chosen benzodiazepine, the use of another cross-tolerant agent at low dose may be valuable. Phenobarbital has a relatively slow onset of action, about 10 minutes, and a long duration of effect that allows gradual self-tapering. Phenobarbital is more likely to cause excessive sedation and respiratory depression and monitoring is important. For patients with sedative–hypnotic withdrawal resistant to benzodiazepines and barbiturates, propofol by bolus (20 mg/dose) or titrated infusions will almost always be successful. However, its use requires high-level monitoring and typically mechanical ventilation.

Withdrawal seizures should also be treated with benzodiazepines or barbiturates. Phenytoin is ineffective in treating or preventing withdrawal seizures and should be reserved for patients with an

underlying seizure disorder who require maintenance phenytoin therapy.

Neuroleptics such as the phenothiazines and butyrophenones (e.g., haloperidol) should not be used alone for sedative-hypnotic withdrawal. Although useful for severe agitation, these neuroleptics are not cross-tolerant with ethanol or sedative-hypnotics, do not prevent or suppress withdrawal, and may result in hypotension, impaired thermoregulation, a lowered seizure threshold, and dystonic reactions. Uncontrolled clinical experience suggests that neuroleptics may be adjunctive therapy for patients with refractory agitation and hallucinations and in treating concomitant nausea, vomiting, and GI cramps.

Sympatholytic therapy with β-blockers (e.g., propranolol) and central adrenergic agonists (e.g., clonidine, dexmedetomidine) has been used for sedative-hypnotic withdrawal, but have certain disadvantages. Sympatholytics are not cross-tolerant with sedative-hypnotics and do not prevent agitation, confusion, or seizures. Moreover, their ability to normalize vital signs may mask a deteriorating clinical situation.

Once withdrawal is controlled, the dose of sedative-hypnotic should be gradually reduced over a period of 3 weeks to 3 months, depending on the dosage and duration of prior use. To avoid precipitating another episode of withdrawal, the dose should generally be tapered by no more than 10% a day although in outpatient practice it is done considerably more slowly.

The approach to GHB withdrawal is similar to that for other sedative-hypnotic withdrawal. Severe cases are often resistant to benzodiazepine treatment and require barbiturates or propofol. Neuroleptics should be avoided if possible.

Reinstitution of baclofen is the initial step in the management of baclofen withdrawal. For patients exhibiting symptoms and signs of more significant withdrawal, high-dose IV benzodiazepine treatment in addition to resumption of baclofen may be required. For patients with acute opioid withdrawal, administration of an opioid treats both the physiologic effects of withdrawal and the psychological effects, particularly craving. Methadone, 10 mg IM or PO can be

administered in the ED, but it should not be prescribed for use after discharge. Parenteral administration guarantees absorption in the vomiting patient. Symptomatic improvement usually occurs within 30 to 60 minutes. Buprenorphine suppresses opioid withdrawal and the associated cravings and some EDs initiate buprenorphine therapy in the ED with prearranged follow-up in a buprenorphine clinic (7). Special credentialing is required to use buprenorphine in the treatment of opioid detoxification.

The decision to administer an opioid is based on clinical and social circumstances, and it is not uniformly done, especially since opioid withdrawal is not medically life-threatening. Clonidine may offer symptomatic relief because it decreases sympathetic activity in the locus ceruleus, although it does not eliminate craving. An initial oral dose of 0.1 to 0.2 mg is recommended. Because hypotension may be particularly problematic after the first dose, the blood pressure should be monitored for 2 hours while the patient remains in the ED. A dose of 0.1 to 0.2 mg every 4 to 6 hours may help prevent recurrence of opioid-withdrawal symptoms.

Detoxification is generally not initiated in the ED and requires referral to an appropriate facility. Federal regulations restrict the use of methadone for detoxification or maintenance to Substance Abuse and Mental Health Services Administration's (SAMHSA) designated programs. Rapid and ultrarapid opioid detoxifications for inpatients followed by naltrexone maintenance therapy have also been used in recent years. These controversial techniques utilize antagonist-precipitated opioid withdrawal as a quick "cure" for opioid dependence. Complications include persistent withdrawal symptoms, pulmonary edema, and death (8).

Reinstitution of drug therapy and gradual tapering of the dose is recommended for antidepressant discontinuation syndrome. Benzodiazepines can be used for signs and symptoms of adrenergic hyperactivity. The treatment of cocaine withdrawal is supportive.

CRITICAL INTERVENTIONS

- Administer diazepam or other long-acting benzodiazepine to patients with sedative-hypnotic withdrawal, adding barbiturates

or propofol for refractory cases.
- Administer opioids, such as methadone or buprenorphine, for the acute manifestations of opioid withdrawal. Clonidine and benzodiazepines are alternatives.

DISPOSITION

Patients with moderate to severe sedative–hypnotic withdrawal should be admitted. Because withdrawal usually persists for several days, admitted patients should be closely monitored for signs of progression and treated as necessary. The level of care depends on clinical severity. Because of potential complications, patients requiring IV sedation are best managed in an intensive or intermediate care unit. Patients with less severe withdrawal may be managed and observed on a medical floor, psychiatric floor, hospital-based detoxification unit, or detoxification unit outside of the hospital. Patients with mild withdrawal may also need to be admitted for the evaluation and treatment of concomitant medical problems that have not been adequately addressed. An inpatient setting, including detoxification, provides a protected environment away from the temptations of illicit drug use.

Outpatient management should be attempted only if the patient can be discharged home with a supportive family member or friend and appropriate outpatient follow-up can be arranged. Supervised withdrawal in the home setting, under the direction of a visiting nurse, may be appropriate in some of these circumstances.

Patients who present to the ED with opioid withdrawal may be discharged home if they do not have other concomitant medical problems that require hospital admission and they can tolerate oral fluids. Offering the patient a limited supply of clonidine (if tolerated in the ED) may help prevent further withdrawal symptoms. Prescriptions for opioids should not be given. A brief intervention and referral to a treatment program is strongly recommended.

Social service, detoxification, or substance-abuse counseling and psychiatric referrals should be offered to all patients with a history of substance abuse.

Common Pitfalls

- Failure to consider the possibility of drug withdrawal in patients with signs and symptoms of adrenergic hyperactivity.
- Failure to appreciate that sedative-hypnotic withdrawal is potentially life-threatening, whereas abstinence-induced opioid withdrawal, although uncomfortable, does not cause significant morbidity.
- Failure to appreciate that neuroleptics do not cross-react with sedative-hypnotics and are not the primary treatment of sedative-hypnotic withdrawal.
- Failure to appreciate that GHB withdrawal may begin within hours of the last dose and be relatively resistant to treatment.
- Failure to appreciate that baclofen withdrawal may occur in the setting of intrathecal baclofen pump dysfunction.

CHAPTER 352 Botulism

Louis Ling

Since 1870, botulism has been the term used to describe the illness associated with food contaminated with *Clostridium botulinum* and its toxin. *C. botulinum* is an anaerobic, spore-forming, gram-positive bacillus. The spores are ubiquitous and can be found in soil, water, and air. Spores are usually dormant and can tolerate 2 hours of boiling at 100°C. Germination of the spores, with resultant toxin formation, requires certain environmental conditions: pH >4.5 and sodium chloride content <3.5%. Unlike the spores, the toxin is heat-labile and can be destroyed by boiling for a few minutes or if heated for 5 minutes at 85°C. Low pH does not inactivate or destroy any preformed toxin.

Botulinum toxin is considered the most lethal substance known, with an estimated oral LD_{50} of 1 μg/kg in humans. Botulinum toxin enters presynaptic nerve terminals via endocytosis, where it irreversibly prevents the release of acetylcholine by inhibiting calcium-dependent exocytosis (1). The net result is a decrease in the acetylcholine concentration within the synaptic cleft both in the autonomic nervous system, resulting in anticholinergic symptoms (muscarinic and nicotinic) and yielding a flaccid paralysis at neuromuscular junctions.

Eight different serotypes of botulinum toxin have been identified (types A–H). Of these, subtypes A, B, and E are of clinical concern and have distinctive geographic distributions. Type A is found predominantly west of the Mississippi, type B predominantly east of the Mississippi, and type E in the Pacific Northwest, especially in

Alaska (2). During summer 2007, an outbreak of type A botulism affected eight patients from Indiana, Ohio, and Texas, who all ate contaminated commercial hotdog chili sauce that was improperly canned in Georgia. However, the vast majority of foodborne botulism is from ingesting home-processed foods (2).

Types A and B are typically found in improperly processed meats and vegetables (3). The food usually appears foul and may have an odor. By contrast, type E does not alter the smell or appearance of food. Human intoxications have been well documented with serotypes A, B, E, and rarely F. Type A accounts for more than one-third of the foodborne cases. Types C cause disease in birds, Type D in cattle, and disease with type G has yet to be documented in either humans or animals in the United States. Type H was identified along with type B in 2013 from an infant and its impact is yet unknown (4).

There are about 145 reported cases of botulism in the United States each year. Classically, there are four distinct diseases as a result of *C. botulinum:* (a) foodborne (adult) botulism occurs after consumption of preformed toxin and accounts for 15% of botulism cases. Smoked or salted meats and fish as well as canned vegetables are typical sources. Mortality ranges from 5% to 10%. (b) Infant botulism, under 1 year of age, occurs after ingestion and propagation of *C. botulinum* in the intestinal tract and accounts for 65% of cases. The vast majority of cases are a result of serotypes A (47%) or B (52%). It follows the ingestion of *C. botulinum* with toxin formation and absorption in the gut lumen (5). The gastrointestinal tracts of infants lack some of the bile acids and gastric acids that normally inhibit clostridial growth. Honey and corn syrup have been identified as sources of *C. botulinum* spores. Vacuum cleaner dust and soil have also been implicated. In the food samples tested, no preformed toxin has been identified, only clostridium spores. About 70% of cases are in breast-fed infants; presumably these infants have different gut flora when compared with their formula-fed counterparts. Almost half the cases reported over the past 30 years have been from California (2). (c) Wound botulism accounts for about 10% of cases and occurs after a wound that is

contaminated with spores that germinate and produce toxin over time. Most cases are associated with black tar heroin made in Mexico, affecting the western United States with the preponderance from California. In one report, only 1 out of 102 cases of wound botulism did not occur in a drug user (6). (d) Botulism of undetermined origin is the adult version of infant botulism, in which no food vehicle can be identified and there is no evidence of wound botulism in a patient older than 1 year of age. This type is rare and usually results from intestinal colonization in an adult.

The World Health Organization describes three more types of botulism in addition to the four classic forms (1): (e) Inhalational botulism is a potential threat if the toxin is aerosolized as a biologic weapon. (f) Waterborne botulism is only a theoretical concern, as water-treatment processes inactivate the toxin. (g) Iatrogenic botulism stems from the use of botulinum toxin for therapeutic or cosmetic purposes (11).

CLINICAL PRESENTATION

The initial symptoms of *foodborne botulism* are predominantly gastrointestinal, including nausea, vomiting, abdominal pain, and distention, likely a result of pathogenic agents or toxins in the contaminated food other than *C. botulinum.* Symptoms usually develop within 12 to 36 hours but may develop as early as 4 hours or as late as 10 days. Other initial symptoms are often mild and include fatigue, weakness, and vertigo. Additional symptoms include sore throat, dry mouth, and poor visual accommodation. If the toxin exposure is minimal, patients gradually recover. Otherwise, symmetric, descending flaccid paralysis with prominent bulbar palsies such as diplopia, dysarthria, dysphonia, and dysphagia develops. Physical examination may reveal weakness or paralysis of the upper extremities; dilated, nonreactive pupils; and ophthalmoplegia. The patient may be drooling and have difficulty speaking. Deep tendon reflexes are preserved, and ataxia is absent. Weakness of the extremities and paralysis of respiratory muscles are the most concerning symptoms. Patients maintain a normal mental

status and are afebrile. Autonomic instability, such as orthostatic hypotension, also occurs and may be the predominant or only symptom on presentation, confounding the diagnosis.

Infant botulism is characterized by constipation followed by neuromuscular paralysis. Cranial nerves are affected first, and paralysis progresses to peripheral and respiratory musculature. The term "floppy infant syndrome" best describes the presentation. Symptoms can vary from mild lethargy with poor feeding to hypotonia with respiratory compromise.

The neurologic symptoms of *wound botulism* are identical to that of foodborne botulism; however, gastrointestinal symptoms are absent. Wounds are typically in avascular areas, with crush injuries, and most often, in patients injecting black tar heroin subcutaneously (skin popping). *Iatrogenic cases* may vary from mild symptoms to profound respiratory compromise requiring intubation. Botulinum toxin is used therapeutically for spasticity, cervical dystonia, blepharospasm, and hyperhidrosis, as well as for cosmetic purposes. The history of recent botulinum toxin injection will make the diagnosis (7).

DIFFERENTIAL DIAGNOSIS

Regardless of the type of botulism, the neurologic manifestations are similar. The diagnosis is easier with large outbreaks; however, the majority of cases involve single patients. As a result, the diagnosis is often missed. Botulism should be considered in a patient presenting with gastrointestinal, autonomic, and cranial nerve dysfunction or in an infant with diminished sucking, feeding, and crying ability. The differential diagnosis for foodborne and infant botulism is listed in Table 352.1. Psychiatric illness should be a diagnosis of exclusion. Misdiagnosis as such has been fatal.

TABLE 352.1
Differential Diagnosis for Botulism

Foodborne Botulism	Infant Botulism
Cerebrovascular ischemia (CVA)	Electrolyte abnormalities
Chemical intoxication	Leigh disease[a]
Carbon monoxide	Meningitis
Barium carbonate	Metabolic encephalopathy
Methyl chloride	Myopathy (congenital)
Methyl alcohol	Reye syndrome
Cholinergic (organophosphate) agents	Sepsis
Diphtheria	Werdnig–Hoffman disease[b]
Elapidae envenomation (coral snake)	
Food poisoning	
Landry–Guillain–Barré syndrome	
Miller–Fisher variant	
Medication reactions (especially aminoglycosides)	
Multiple sclerosis	
Myasthenia gravis	
Eaton–Lambert syndrome	
Paralytic shellfish poisoning	
Poliomyelitis	
Polymyositis	
Psychiatric disorders	

[a]Subacute necrotizing encephalomyelopathy.
[b]Spinal muscular atrophy.

The gastrointestinal symptoms of botulism are nonspecific and do not demonstrate a distinctive pattern. Patients at this stage of the disease are often discharged with a diagnosis of food poisoning. Fever is absent in patients with botulism but can be present in certain types of food poisoning. A history of the consumption of canned foods, especially home-canned foods, may be helpful in arriving at the diagnosis.

Landry–Guillain–Barré syndrome usually results in ascending weakness or paralysis. In the Miller–Fisher variant of this syndrome, patients have bulbar palsies (diplopia, dysarthria, dysphonia, and dysphagia) and descending weakness or paralysis, making it extremely difficult to distinguish clinically from botulism. Gastrointestinal symptoms are lacking in Landry–Guillain–Barré

syndrome, unless they are part of the associated antecedent viral syndrome.

Myasthenia gravis may present as weakness, ptosis, and ophthalmoplegia; however, gastrointestinal symptoms are absent. A Tensilon (edrophonium) test may be necessary to differentiate myasthenia gravis from botulism (see Chapter 160). Edrophonium blocks the metabolism of acetylcholine in the synapse and has less effect in botulism, in which there is decreased neurotransmitter release, although some degree of clinical improvement may occasionally be seen.

The Centers for Disease Control and Prevention (CDC) criteria for the diagnosis of botulism requires a patient who presents with descending paralysis to have one of the following: *C. botulinum* isolated from stool or wound specimens; botulinum toxin in serum, stool, or implicated food samples; or a compatible illness in a person who is epidemiologically linked to a case confirmed by the previous methods (7). Although not included in the CDC diagnostic criteria, electromyography demonstrating findings typical of botulism may be required in order for antitoxin to be released. Botulism demonstrates a typical pattern on repetitive stimulation test (20 to 50 Hz) (8). Although this pattern is not pathognomonic for botulism, when it is combined with other clinical data it can be used to make the diagnosis.

ED EVALUATION

The history should include the time of onset; nature, progression, and severity of symptoms; and questions concerning diet, crush injuries, skin wounds, and injected drugs. The physical examination should focus on neurologic evaluation, particularly cranial nerve function, muscle strength, deep tendon reflexes, pupil size and reactivity, extraocular motor function, swallowing, and phonation. As death from botulism is from respiratory insufficiency, patients should have frequent assessments of vital capacity and negative inspiratory force.

Cell counts, serum electrolytes, and plain radiographs are usually normal in patients with botulism but may be helpful to exclude other diagnoses. Normal cerebrospinal fluid or slightly elevated spinal fluid protein may be seen in botulism and distinguishes it from other disease states such as meningitis. Landry–Guillain–Barré syndrome may reveal elevated protein without pleocytosis, but early in that syndrome the spinal fluid may be normal. Brain imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) is normal in patients with botulism but may yield the diagnosis of cerebral or cerebellar infarct.

The Tensilon test can help differentiate myasthenia gravis from botulism.

When botulism is suspected, electromyography should be performed as soon as possible.

Stool, serum, or wound cultures should be sent for *C. botulinum* to the state health department laboratory or the CDC. Serum and stool samples and wound tissue should also be sent for detection of botulinum toxin. In one study, at least one of these laboratory tests was positive in 65% of patients diagnosed with botulism. Stool and sera should be refrigerated but not frozen. Wound specimens should be placed in an anaerobic device. Suspected food should be left in their original containers and placed in sterile unbreakable containers if possible. Currently, the mouse bioassay used to detect botulinum toxin is complicated, and results are often delayed. Rapid assays under development may allow for more rapid confirmation (5).

KEY TESTING

- Supportive care testing for electrolytes, complete blood count (CBC), calcium, magnesium
- Lumber puncture (LP), Tensilon test, and brain imaging to investigate other potential causes
- Electromyography (EMG) is the fastest test to suggest botulism
- Send serum, stool, wound, and food samples to state laboratory or CDC for confirmation

ED MANAGEMENT

Supportive care is the mainstay of treatment. Endotracheal intubation with mechanical ventilation is recommended for patients with a vital capacity $<30\%$ of predicted (or <12 mL/kg). Fluids should be given to replete any gastrointestinal losses, and parenteral analgesics can be given for the pain associated with abdominal distention.

Despite the delay from ingestion of contaminated food to presentation, gastric decontamination should be considered in cases of foodborne botulism. Gastric lavage may remove any remaining toxin or contaminated food from the stomach. Activated charcoal has been shown to reduce morbidity and mortality in animals (9). Only sorbitol-based cathartics should be used, as magnesium may exacerbate weakness. Although whole-bowel irrigation can aid in removal of toxin from the gut, this has not been evaluated in a formal study.

A heptavalent (types A–G) botulism antitoxin (HBAT) has been developed by the US Army and was approved by the FDA in 2013 to replace previous monovalent and bivalent antitoxin preparations for patients older than 1 year (10). The equine-derived antitoxin is distributed by the CDC to nine local repositories in the United States and is available by contacting the state health department. Antitoxin is most effective when given within 24 hours of symptom onset and should be administered as soon as the diagnosis of botulism is suspected, without waiting for laboratory confirmation. The antitoxin does not reverse symptoms already present on administration. It can only prevent symptom progression, further stressing the necessity of early administration.

The initial dose of HBAT is one vial diluted 1:10 given intravenously, slowly to observe for allergy and adverse effects. The benefits of antitoxin therapy must be weighed against the potential adverse effects. Because antitoxin is an animal-derived biologic product, its use can result in anaphylaxis, hypersensitivity reactions, and serum sickness. It is not recommended to administer a test dose to assess hypersensitivity, because botulism can be fatal and

antitoxin is the only available therapy. Clinicians should be prepared to handle any adverse reactions and should have appropriate medications (e.g., epinephrine) readily available.

A human botulism immune globulin (Baby-BIG) was approved by the FDA in 2013 but it is in use for many years for infant botulism. It is only available from the California Department of Health Services Infant Botulism Treatment and Prevention Program.

Antibiotics should be administered for wound botulism. Penicillin G is usually the first-line agent, although many antibiotics have been shown to be effective against *C. botulinum*. Early surgical consultation should also be obtained for cases of wound botulism because debridement is considered a primary therapeutic intervention (8).

In contrast, antibiotics are not generally recommended for infant botulism. Aminoglycosides have been demonstrated both clinically and experimentally to potentiate neuromuscular blockade. Use of antibiotics in infant botulism can exacerbate the condition, as lysis of intraluminal *C. botulinum* may increase the amount of toxin absorbed (2). The benefit of antibiotic therapy for foodborne botulism has not been demonstrated and it is thus not recommended.

CRITICAL INTERVENTIONS

- Consider adult botulism when there is a history of ingestion of smoked, salted, or canned food.
- Consider infant botulism in a floppy baby with respiratory insufficiency.
- In cases of suspected wound botulism, consult a surgeon regarding debridement.
- Assess the vital capacity in patients with suspected botulism and perform endotracheal intubation on those with a vital capacity $<30\%$ of predicted (<12 mL/kg).
- Contact the state department of health or the CDC (770-488-7100) and administer botulism antitoxin as soon as possible.

DISPOSITION

Any patient suspected of having botulism should be admitted to a critical care setting. This allows for observation, frequent neurologic examinations, assessments of respiratory status, and monitoring for anaphylaxis, which is a risk with the administration of the antitoxin.

Consultants from infectious disease, toxicology, critical care, and neurology may aid in diagnosis and assumed care. Patients need frequent respiratory evaluations and should be admitted to an intensive care unit. Early surgical consultation should be obtained for cases of wound botulism because debridement is considered a primary therapeutic intervention (8). Contact with the state health department or CDC Emergency Operations Center (770-488-7100, available 24 hours a day) is also required as soon as possible to allow for early administration of antitoxin.

Prolonged admission is the usual course, as the recovery period can last from weeks to months and occasionally up to a year, but mortality has fallen from 50% to less than 5% currently for untreated cases. Patients who receive early and aggressive supportive care usually do well. Although patients can make a complete recovery, long-term sequelae are common and range from fatigue to persistent muscle weakness and dyspnea.

Common Pitfalls

- Failure to consider the diagnosis of botulism in patients with diplopia, dysphagia, dysphonia, and weakness, or in infants with constipation, feeding problems, and hypotonia.
- Failure to adequately monitor for respiratory insufficiency.
- Failure to appreciate that electromyography is the most rapidly available diagnostic test.
- Failure to appreciate that early antitoxin administration is the best therapy.
- Failure to administer antitoxin pending results of a test dose to assess for hypersensitivity.

ACKNOWLEDGMENTS

The author would like to thank Dr. Adhi Sharma for his contributions to previous editions of this chapter.

CHAPTER 353

Oral Hypoglycemic Agents

Jeffrey R. Suchard

Diabetes mellitus is a common disease, with most patients having the noninsulin-dependent (Type II) form of the disease. Oral drug therapy is the main treatment modality in these patients. Several oral medications may be used, including the sulfonylureas, meglitinides, biguanides, α-glucosidase inhibitors, dipeptidyl peptidase inhibitors, and thiazolidinediones, which are collectively known as the "oral hypoglycemic agents." Of these drug classes, only the sulfonylureas and meglitinides are truly hypoglycemic agents, for they will lower the serum glucose concentration; the other classes have various mechanisms to improve glucose levels and tolerance but do not generally cause hypoglycemia by themselves. Sulfonylurea agent exposures result in the most medical evaluations, but biguanide toxicity causes the most reported deaths; this chapter will therefore focus mostly on these classes of drugs. Hypoglycemia in general is covered in Chapter 206.

The pharmacokinetics of oral antidiabetic medications are summarized in Table 353.1. Sulfonylurea agents inhibit potassium efflux from pancreatic β-islet cells, depolarizing the cell and triggering endogenous insulin release (1). Long-acting agents, such as glyburide, chlorpropamide, and extended-release glipizide, are more likely to result in hypoglycemia requiring hospital admission (2). Additional risk factors for hypoglycemia with sulfonylurea use include greater patient age, concurrent polypharmacy, and impaired renal clearance.

TABLE 353.1
Pharmacokinetics of the Hypoglycemic Agents

Generic Name	Trade Name	Peak (hrs)	Duration (hrs)
First-Generation Sulfonylureas			
Chlorpropamide	Diabinese	3–6	24–72
Acetohexamide	Dymelor	3	12–24
Tolazamide	Tolinase	4–6	12–24
Tolbutamide	Orinase	5–8	6–12
Second-Generation Sulfonylureas			
Glipizide	Glucotrol	1–3	12–24
Glipizide ER	Glucotrol XL	6–12	24
Glyburide	Micronase, DiaBeta Glynase	2–6	24
Glimepiride	Amaryl	2–3	24
Meglitinides			
Repaglinide	Prandin	0.5–1	1
Nateglinide	Starlix	0.3	1.5
Biguanides			
Metformin	Glucophage	2–3	5–6

In overdose situations, whether intentional or accidental, hypoglycemia may be expected with any of the sulfonylureas. If hypoglycemia occurs, it is typically within the first several hours after overdose. In adult volunteers ingesting glipizide, all subjects became hypoglycemic within 3 hours (3), and the mean time to hypoglycemia was 2 hours in a retrospective study of children <6 years old (4). Allowing these children access to food or prophylactic treatment with IV glucose increased the delay to hypoglycemia, when it occurred, to over 5 hours. A significant proportion (18%) of these patients with access to food had a delay to hypoglycemia >8 hours after sulfonylurea ingestion (4). Occasional cases of delayed hypoglycemia more than 24 hours after drug ingestion have been reported (5).

Meglitinides are a newer family of agents used to treat postprandial hyperglycemia. These drugs are derivatives of the nonsulfonylurea moiety of glyburide and include repaglinide

(Prandin or NovoNorm) and nateglinide (Starlix). These drugs have a similar mechanism of action to the sulfonylureas, although the time to onset and the duration of hypoglycemia are much shorter (Table 353.1) (1).

The biguanide class includes the drugs metformin and phenformin. Metformin is currently the only biguanide in common use, and it is the most commonly prescribed medication worldwide. Metformin increases insulin sensitivity and decreases hepatic gluconeogenesis and intestinal glucose absorption, without affecting insulin secretion. Metformin is often referred to as an antihyperglycemic medication because it corrects hyperglycemia in diabetics but does not cause hypoglycemia in nondiabetics. Hypoglycemia associated with metformin is rare and usually only occurs in the presence of other medications interfering with glucose homeostasis (6).

Lactic acidosis is the most serious side effect associated with metformin use. Metformin-associated lactic acidosis (MALA) occurs with an incidence of 0.03 cases per 1,000 patient-years and carries a mortality rate of 50% (7). Because lactic acidosis occurs mainly in patients with baseline renal insufficiency, metformin is contraindicated in patients with serum creatinine >1.5 mg/dL (7). Use of iodine-containing contrast media has been linked to MALA, leading the manufacturer to recommend that the drug should be discontinued 48 hours prior to IV contrast and withheld for the next 48 hours. MALA after contrast radiography appears to occur mostly in patients with underlying renal insufficiency. Lactic acidosis also occurs with acute metformin overdose.

The other classes of oral drugs used for diabetes are rarely associated with side effects that do not cause hypoglycemia and rarely need emergency department (ED) care.

CLINICAL PRESENTATION

Symptoms from hypoglycemia fall into two main categories: autonomic and neuroglycopenic. Autonomic symptoms are a result of excessive adrenergic tone, resulting from the release of counter-

regulatory hormones as the body reacts to increased serum glucose. Anxiety, palpitations, diaphoresis, irritability, and tremor are seen at serum glucose levels near 60 mg/dL in nondiabetic volunteers. Neuroglycopenic symptoms such as dizziness, tingling, blurred vision, difficulty thinking, and faintness begin at glucose levels near 50 mg/dL. However, there is a wide variation in the glucose level at which symptoms develop. Some individuals, particularly women and children, can be asymptomatic with glucose levels <50 mg/dL, and diabetics can develop symptoms of hypoglycemia at a "normal" or elevated glucose level when the level rapidly falls from a higher one. Additionally, concurrent therapy with β-adrenergic blockers or underlying diabetic neuropathy may mask the autonomic symptoms of hypoglycemia.

Hypoglycemia can cause focal neurologic deficits and, in severe cases, coma or seizures. Mild hypothermia may develop with prolonged hypoglycemia. Hypokalemia may result from intracellular potassium shifting.

MALA presents with nonspecific signs and symptoms. Patients may have nausea, vomiting, anorexia, epigastric pain, diarrhea, somnolence, or lethargy. Kussmaul respirations (hyperpnea and tachypnea) represent increased ventilation in response to the metabolic acidosis. Hypotension, hypothermia, and respiratory failure have also been reported. Various cardiac dysrhythmias, including premature ventricular contractions, bradycardia, asystole, and ventricular fibrillation, have been reported, probably secondary to severe acidemia.

DIFFERENTIAL DIAGNOSIS

Hypoglycemia is a potential etiology for any patient with altered mental status, neurologic findings, or signs of sympathetic stimulation such as diaphoresis or tremor. The differential diagnosis of patients with such findings is large and includes trauma, stroke, brain tumors, central nervous system infections, severe metabolic disorders, vasovagal episodes, and a wide variety of drug intoxications. Hypoglycemia should be considered as the underlying

cause for patients presenting with trauma or seizures. Patients particularly at risk are those with a personal or family history of noninsulin-dependent diabetes, with access to oral hypoglycemic drugs.

Diabetics presenting with an elevated anion-gap metabolic acidosis may have either MALA or diabetic ketoacidosis. These conditions may be differentiated based on the history (e.g., intercurrent illness, recent oral intake, intentional ingestion) and the presence or absence of hyperglycemia, ketosis, and hyperlactatemia.

ED EVALUATION

Assessment of the patient's airway, breathing, and circulation is the first priority. The history should differentiate between an overdose or only therapeutic doses, the type of medication(s), the amount ingested, and the time and course of symptoms. Physical examination should pay particular attention to the neurologic status, as hypoglycemia may present with subtle cognitive changes, such as irritability, distractibility, or even focal motor deficits. A rapid bedside glucose test should be performed early in patients with altered mental status.

Laboratory evaluation should include a confirmatory quantitative glucose determination. A serum chemistry panel is also indicated to check for electrolyte abnormalities and renal insufficiency. Repeat bedside glucose determinations should be performed at least every 1 to 2 hours during the initial evaluation and immediately whenever the patient shows signs of any autonomic increase or altered mental status.

Patients with suspected metformin toxicity need a chemistry panel to evaluate for an anion-gap metabolic acidosis and renal insufficiency as well as a serum lactate level. If an elevated anion gap is present, blood gas analysis will help define the degree of acidosis.

KEY TESTING

- Rapid and serial serum glucose determinations, preferably with stat bedside testing
- Chemistry panel, to check for renal insufficiency and/or an elevated serum anion gap
- With metformin toxicity: serum lactate, blood gas analysis

ED MANAGEMENT

Gastrointestinal decontamination with activated charcoal should be considered for patients presenting early after oral hypoglycemic agent ingestion. The first-line treatment for symptomatic hypoglycemia is intravenous (IV) dextrose. Adults should be given 1 to 2 mL/kg of 50% dextrose (typically 1 to 2 ampules D50W); children should receive 2 to 4 mL/kg of 25% dextrose. Repeat dextrose boluses may be necessary, as determined by serial serum glucose determinations, and an infusion of 5% to 10% dextrose can be initiated to maintain euglycemia (60 to 110 mg/dL). If higher dextrose concentrations are required, the infusion should be given via a central venous catheter. The transient hyperglycemia that occurs with bolus dextrose therapy can cause reflex secretion of additional insulin (1), exacerbating the underlying problem and increasing the overall dextrose requirements. Hence, excessive dosing of dextrose should be avoided.

Octreotide, a synthetic somatostatin analog that inhibits pancreatic insulin secretion (1,3,8), is increasingly used as an option for treating refractory or recurrent hypoglycemia as a result of sulfonylurea poisoning. Octreotide is superior to glucose alone in volunteer sulfonylurea overdose by decreasing hypoglycemia, glucose requirements, and circulating-insulin levels (3). In clinical experience, octreotide use significantly decreases recurrent hypoglycemic episodes in patients with sulfonylurea toxicity (8). Dosing of octreotide is not standardized, and it has been given both subcutaneously (SC) and IV. Suggested dosing is 50 to 100 μg SC or IV every 6 to 12 hours for adults and 4 to 5 μg/kg/d divided every 6 hours in children.

No specific therapy exists for MALA. Endotracheal intubation and correction of hypotension with IV fluids and vasopressors are likely to be needed in severe cases. Severe cases can be treated with hemodialysis, which will correct the acidosis as well as remove lactate and metformin.

CRITICAL INTERVENTIONS

- Obtain serial serum glucose levels on patients with potential sulfonylurea and meglitinide overdose.
- Obtain a serum lactate level on patients with metabolic acidosis who are taking metformin.
- Administer IV dextrose for hypoglycemia, but avoid inducing hyperglycemia.
- Administer octreotide to patients with recurrent hypoglycemia.

DISPOSITION

Patients developing hypoglycemia from sulfonylurea drugs should be treated with dextrose and admitted to the hospital. The half-lives of the sulfonylureas are long enough that recurrent episodes of hypoglycemia should be expected. Admission to a critical care unit is often necessary, as the frequency of glucose determinations (at least every 1 to 2 hours) may preclude observation on a general medical ward. Also, patients may require frequent adjustments in dextrose infusions or treatment with octreotide. Extended observation in an ED holding unit may be considered if the patient does not suffer from recurrent hypoglycemia requiring repeat dextrose boluses or infusions. Hypoglycemia from meglitinide toxicity theoretically should be of shorter duration than from sulfonylureas; however, as a result of a lack of published evidence that short-term observation is safe, such patients should be managed like sulfonylurea-toxic patients and be admitted for serial glucose determinations.

There is considerable controversy regarding the optimal management of asymptomatic patients exposed to oral hypoglycemic medications. Many of the patients evaluated for

sulfonylurea toxicity are children in whom the history of actual ingestion (vs. mere exposure to the pills) is unclear, who present with normal mental status and glucose levels, and who generally have a benign outcome. Nevertheless, because rapid drug detection to confirm actual exposure is not commonly available, these patients need a period of observation to monitor for hypoglycemia; the duration of this observation period is the crux of the controversy. Published evidence generally supports an observation period of 8 hours (9). Patients who develop hypoglycemia are treated and admitted, although those who do not manifest hypoglycemia may be discharged home or referred for psychiatric evaluation as appropriate. Prophylactic treatment of asymptomatic euglycemic patients with glucose should be avoided, as this may mask the development of hypoglycemia and lead to an inappropriate disposition. Cases of delayed hypoglycemia from sulfonylurea agents have occurred when the patients have been given parenteral glucose (9). Oral food intake is acceptable and seems less likely to mask hypoglycemic toxicity, although it may just delay its onset by a few hours (4). Because of the required length of observation and the potentially dire CNS consequences of discharging a patient who later becomes hypoglycemic, some authors recommend medical admission and at least 24 hours of observation for all patients with a known or suspected overdose of sulfonylurea drugs.

Patients with MALA also require admission, usually to an intensive care unit, because the associated mortality is high and these patients often have significant comorbidities. Serum lactate and pH levels do not correlate well with clinical outcome (10). Patients with an acute biguanide overdose, but without lactic acidosis, should be admitted for serial serum chemistry determinations.

Patients overdosing with the other oral agents for diabetes are unlikely to require admission, unless concerning co-ingestants or comorbidities are present. Consultation with a poison control center or medical toxicologist can assist in determining the optimal patient disposition.

Common Pitfalls

- Failure to appreciate that hypoglycemia can result in focal neurological deficits and focal seizures.
- Failure to observe patients with sulfonylurea and meglitinide overdose for at least 8 hours.
- Administering prophylactic dextrose to patients with sulfonylurea and meglitinide overdose who are asymptomatic or euglycemic.
- Failure to appreciate that excessive glucose administration promotes insulin secretion and can lead to recurrent hypoglycemia in sulfonylurea and meglitinide poisoning.

CHAPTER 354

Mushrooms

Brandon K. Wills and Steven E. Aks

Serious poisoning from mushroom ingestion is relatively infrequent. Exposures most often involve (1) unintentional ingestion of toxic species obtained by inexperienced foragers, (2) individuals seeking mind-altering effects of some species, or (3) unintentional ingestion by children. Differentiating poisonous from nonpoisonous species can be difficult even for experts and often requires microscopic examination of the spores. For the clinician, evaluating a patient for suspected poisoning, identifying the fungus in question is even more challenging.

In 2011, there were 6,818 exposures to mushrooms reported to US poison centers, which included 5,560 cases of unknown species (1). There were two deaths, both from cyclopeptide species. There are several hundred toxic mushroom species, and these can be categorized into a syndromic presentation based on their mycotoxin (see Table 354.1).

TABLE 354.1
Presenting Symptoms/Signs, and Treatment by Mushroom Species

Predominant Effect	Associated Features	Mushroom Class/Toxin	Species	Treatment[a]
Hallucinations	Mydriasis, tachycardia, coma, seizures	Psilocin	*Psilocybe* and *Concocybe* sp	Benzodiazepines
	Mild hallucinations, coma, myoclonus, seizures	Ibotenic acid/muscimol	*Amanita muscaria, pantheria, gemmata*	Low-stimulus environment
Cholinergic signs	DUMBELS[b]	Muscarine	*Clitocybe* and *Inocybe* sp	Atropine for pulmonary symptoms
Disulfiram reaction	N/V/D, flushing, ↑HR association with ethanol use	Coprine	*Coprinus* sp	Antihistamines
Renal failure	Delayed GI symptoms	Orellanine[c]	*Cortinarius* sp	Supportive/hemodialysis
Renal failure	Early GI symptoms	Allenic norleucine[c]	*Amanita smithiana*	Supportive/hemodialysis
Rhabdomyolysis	Myalgias, fatigue	Unknown myotoxin[c]	*Tricholoma equestre*	Maintenance of urine output, ± urinary alkalinization
Early GI symptoms (2–3 hrs)	N/V/D	GI irritants	*Chlorophyllum* sp, many others	Supportive care only Antiemetics
Delayed GI symptoms (>6 hrs)	Delayed hepatotoxicity	α-Amanitin[c]	*A. phalloides, virosa, Lepiota* sp	Activated charcoal Penicillin G *N*-Acetylcysteine Silibinin Consider liver transplant
	Delayed nephrotoxicity	Orellanine[c]	*Cortinarius*	Supportive/hemodialysis
	N/V/D, CNS, hepatic	Gyromitrin[c] (monomethyl hydrazine)	*Gyromitra* sp	Pyridoxine

[a]In addition to supportive care, including IV fluids and antiemetics, and decontamination if appropriate.
[b]Diarrhea, urination, miosis, bradycardia, bronchorrhea, bronchospasm, emesis, lacrimation, salivation.
[c]Mushrooms that lead to potentially lethal poisoning.

The most deadly class is the cyclopeptide-containing, or amatoxin-containing, Amanita species. Cyclopeptide poisoning is a rare event in the United States, but exposures are much more common in Europe. Amatoxins are classically found in *Amanita phalloides* and *A. virosa* species but are also found in *Galerina autumnalis, G. venenata, Lepiota* sp, and *Conocybe filaris.* Amatoxins are bicyclic octapeptides that noncompetitively inhibit RNA polymerase II in the liver and, to a lesser extent, the kidney. Protein synthesis is interrupted, causing hepatocellular necrosis and acute tubular necrosis. Severe poisoning can result in fulminant hepatic and renal failure. Phallotoxins are another cyclopeptide toxin found in *Amanita* sp, which are thought to produce the gastrointestinal (GI) symptoms seen 6 to 10 hours after ingestion.

Mushrooms containing coprine include members of the *Coprinus* sp, including *C. atramentarius.* Metabolites of coprine can inhibit aldehyde dehydrogenase and result in a disulfiram-like reaction if ethanol is consumed concurrently or within 3 days of the meal (see Chapter 297).

There is a diverse group of mushrooms whose toxins are irritants that cause primarily GI symptoms. Nausea, vomiting, diarrhea, and abdominal pain usually occur within 2 to 3 hours of the meal, and

because the course is generally self-limited, identification of the specific species is unimportant.

Amanita muscaria, A. pantherine, and *A. gemmata* contain the toxins ibotenic acid and muscimol. Ibotenic acid is similar to the excitatory neurotransmitter glutamate and is an agonist at the *N*-methyl-D-aspartate (NMDA) receptor, whereas muscimol is a γ-aminobutyric acid (GABA) agonist. Symptoms can be diverse and may include somnolence, hallucinations, myoclonus, and seizures. Patients may seek to consume *A. muscaria* and *A. pantherine* species intentionally for their hallucinogenic effects.

Gyromitra esculenta or "false morel" and other species represent one-third of fatal mushroom poisonings in Eastern Europe; however, they are quite rare in the United States. These mushrooms contain gyromitrins, a family of hydrazones that are metabolized to monomethylhydrazine, which is structurally related to isoniazid and some types of rocket fuel. Hydrazines inhibit pyridoxine phosphokinase, which prevents the activation of pyridoxine (vitamin B_6). Activated B_6 is required for GABA synthesis, resulting in decreased GABA production. Poisoning results in delayed GI symptoms and hepatic and renal toxicity, and like isoniazid, often include seizures (see Chapter 317).

Muscarine is an alkaloid found in both *Clitocybe* and *Inocybe* genera that is structurally similar to acetylcholine. Symptoms are typically less severe than, yet similar to, the peripheral muscarinic effects seen in organophosphate/carbamate insecticide exposures (see Chapter 318).

Species of *Cortinarius* contain the toxin orellanine, whose metabolites cause damage to renal tubules and result in interstitial nephritis and renal failure several days to weeks after ingestion. The majority of these cases have been in Europe.

A. smithiana mushrooms contain alienic norleucine and pentanoic acid, which can cause renal failure several days after ingestion. Unlike *Cortinarius,* these mushrooms may cause GI effects as early as 2 hours of ingestion.

Psilocybe species, as well as *Concocybe smithii, Gymnopilus spectabilis,* and *Panaeolus subbalteathus,* are all known to contain

psilocybin. Ingestion of this class of mushroom is often intentional for its hallucinogenic effects. Psilocin is a serotonin agonist that often causes an initial sympathomimetic-like effect including tachycardia, hypertension, mydriasis, and tremor, followed by hallucinations.

Rhabdomyolysis has been attributed to a myotoxin found in *Tricholoma equestre* mushrooms.

CLINICAL PRESENTATION

Patients often present within several hours of a mushroom meal with nonspecific GI symptoms including nausea, vomiting, and diarrhea. Fortunately, the majority of these patients are suffering from GI irritants and require only supportive care. Patients who have consumed the more toxic mushrooms containing cyclopeptides, orellanine, or monomethylhydrazine generally have a delay of more than 6 hours before the onset of symptoms. A short time to symptom onset gives the clinician some reassurance that patients presenting early are likely to have a benign clinical course. A notable exception is with *A. smithiana* ingestion; patients ingesting this mushroom are likely to have GI symptoms within hours of ingestion but subsequently develop renal failure over the next 48 hours to several weeks. Fortunately, *A. smithiana* ingestions are rare, and the only cases reported in the United States have been in the Pacific Northwest. Another caveat applies to those who have consumed a "mushroom salad" that contained several species including both cytotoxic and GI irritant species and thus present with symptoms earlier than 6 hours.

Each class of toxic mushroom has a distinctive constellation of presenting symptoms, signs, laboratory abnormalities, and end-organ involvement (Table 354.1). Patients who have ingested cyclopeptide- or amatoxin-containing mushrooms will typically present after more than 6 hours of ingestion with nausea, vomiting, abdominal pain, and severe watery diarrhea. Symptoms may improve 24 to 48 hours into the illness, followed by hepatic injury marked by elevated transaminases, bilirubin, and often renal dysfunction (2). Within 2 to 6 days, fulminant hepatic and renal failure may develop, with subsequent hepatic encephalopathy, coagulopathy, seizures, and

death. With intensive supportive therapy, survival may be as high as 90% (3); however, with fulminant hepatic failure, orthotopic liver transplant may be required (4).

Mushrooms containing coprine are typically edible and cause no symptoms. If ethanol is consumed between several hours to 3 days after the ingestion, however, a disulfiram-like reaction may be seen. Symptoms include nausea, vomiting, facial flushing, hypotension, tachycardia, headache, vertigo, and metallic taste. Symptoms typically last up to several hours.

Mushrooms containing GI irritants cause symptoms similar to gastroenteritis, usually beginning 30 minutes to 6 hours after ingestion. Vomiting and diarrhea, sometimes bloody, may last for 48 hours and are typically self-limited.

Patients consuming mushrooms containing ibotenic acid and muscimol can have a varied presentation as a result of both GABAergic and glutamate effects. Symptoms usually begin within 30 to 180 minutes of ingestion and may include a combination of euphoria, mild hallucinations, obtundation, agitation, myoclonus, and seizures.

The “false morel” *G. esculenta* is often confused with the edible true morel or *Morchella* species and results in significant toxicity. The severity of symptoms depends on the amount ingested and method of preparation. Parboiling or drying may eliminate the gyromitrin toxins. Patients often become symptomatic 5 to 8 hours after ingestion and present with nausea, vomiting, and diarrhea. These symptoms may last up to several days before resolving. Central nervous system (CNS) effects, including fatigue, headache, ataxia, tremor, and (rarely) seizures, may be seen. After 24 to 72 hours, there may be evidence of hepatic and/or renal damage, as well as hemolysis and methemoglobinemia.

The onset of symptoms following ingestion of muscarine-containing mushrooms is rapid, usually within 30 minutes. Cholinergic signs and symptoms include those identified by the commonly used mnemonic DUMBELS: diaphoresis, urination, miosis, bronchorrhea/bradycardia, emesis, lacrimation, and salivation. With

supportive treatment, patients typically recover with no long-term effects.

Rhabdomyolysis with myalgias, weakness, and fatigue begins 24 to 74 hours after ingesting *T. equestre* mushrooms. Symptoms usually improve over the following 2 weeks, but death can occur. Fatal cases have had persistent creatine kinase (CK) elevations and evidence of myocardial damage on autopsy.

Toxicity from orellanine-containing *Cortinarius* sp is most often seen in Europe and is relatively uncommon in the United States. GI symptoms, including nausea, vomiting, diarrhea, and abdominal or flank pain, begin 2 to 14 days after ingestion, at which time renal damage has already occurred. Progression to end-stage renal failure may ensue.

Similar to poisoning by *Cortinarius* sp, the ingestion of alienic norleucine–containing *A. smithiana* produces renal damage 2 to 4 days after ingestion. One distinguishing feature is that *A. smithiana* may cause early GI symptoms.

Abuse of psilocin-containing mushrooms is common among young adults, frequently in combination with alcohol and other drugs. Patients often present to the emergency department with severe anxiety from the unpleasant hallucinations. Other signs and symptoms may include mydriasis, tachycardia, GI symptoms, coma, and seizures. As with other hallucinogens, an increased association with high-risk behavior and poor decision-making often leads to other traumatic injuries (see Chapter 346, “Hauucinogens”).

DIFFERENTIAL DIAGNOSIS

Toxic mushroom ingestion should be considered in the differential diagnosis of patients presenting with GI symptoms, hepatic or renal damage, delirium or hallucinations, disulfiram-like reactions, seizures, or rhabdomyolysis. The GI symptoms from both GI irritant and the more toxic mushrooms will often be indistinguishable from gastroenteritis. The history of recent wild mushroom ingestion may be the only clue to the diagnosis.

Hepatotoxicity similar to that caused by *Amanita* ingestion can occur with overdose of acetaminophen and iron, chronic isoniazid

(INH) therapy, and many nontoxicologic etiologies, including viral hepatitis. In addition to coprine-containing mushrooms, a large number of chemicals and pharmaceuticals can cause a disulfiram-like reaction when ethanol is consumed (see Chapter 297). Other hallucinogens, CNS depressants, γ-hydroxybutyrate (GHB), or withdrawal syndromes may cause symptoms similar to those seen after the ingestion of mushrooms containing ibotenic acid and muscimol. Agents causing toxicity similar to hydrazine-containing mushrooms include isoniazid and some types of rocket fuel. Direct muscarinic agonists or acetylcholinesterase inhibitors produce cholinergic toxicity similar to that seen with muscarine-containing mushrooms. The differential diagnosis of renal failure includes prerenal causes, intrinsic nephrotoxins, and postrenal causes. Conditions that may be confused with psilocin intoxication include use of LSD, mescaline, morning glory, hallucinogenic amphetamines (e.g., methylenedioxymethamphetamine [MDMA]), synthetic cathinones, tryptamines (e.g., dimethyltryptamine [DMT]); alcohol withdrawal; or medical causes of delirium.

ED EVALUATION

The goal of evaluation is to identify patients who may have ingested a cyclopeptide, amatoxin, or other potentially dangerous mushroom. Of greatest importance is the time interval between ingestion of the mushroom and the onset of GI symptoms. Other information that may be helpful include the quantity consumed, cooked versus raw, fresh versus dried, and if ethanol was consumed within 3 days of the meal. Positive identification of the mushroom involved will be very difficult but may be possible if the patient brings a sample of the offending mushroom. The Illinois Poison Center can consult a mycologist to review digital images of the mushroom in three planes that the physician has sent electronically to the poison center (5). The mushroom does not have to be positively identified if the most toxic species can be ruled out. Contacting a regional poison center (800-222-1222) can be helpful in this regard.

Patients with prolonged GI symptoms or clinical evidence of dehydration should have measurement of serum electrolyte, blood

urea nitrogen (BUN), creatinine, and glucose as well as a urinalysis. Evaluation of patients presenting with weakness or myalgias should include a serum creatine phosphokinase (CK). Those with possible amatoxin poisoning should have liver function tests, chemistries, and coagulation studies. A serum creatinine >1.2 mg/dL with an international normalized ratio (INR) >2.5 may predict mortality (6). Except for muscarine, which can be identified by thin-layer chromatography, other mushroom toxins are not easily detected by routine toxicology screening. Thus, the best strategy is to have the mushroom in question identified by a mycologist.

KEY TESTING

- Mushroom identification if possible
- For dehydrated patients: serum electrolytes, BUN, creatinine, urinalysis
- For patients with weakness or myalgias: CK
- For suspected cyclopeptide exposure: transaminases, INR

ED MANAGEMENT

Supportive care is the mainstay of management for any toxic mushroom ingestion. Most patients will need no treatment other than intravenous (IV) fluids if dehydrated and antiemetics. Benzodiazepines should be administered for seizures, severe agitation, or hallucinations. Activated charcoal should be considered for patients presenting within 1 to 2 hours of ingestion.

There is no clear antidote for amatoxin-containing mushrooms though many therapies are empirically used (7). Multiple-dose activated charcoal has been recommended because amatoxins are enterohepatically recirculated. Charcoal hemoperfusion may also enhance toxin elimination if performed in the first 24 hours. High-dose IV penicillin (1 million units per kilogram per day for the first day, followed by 0.5 million units per kilogram per day for 2 more days) appears to have variable efficacy. The mechanism is postulated to prevent or reduce hepatic uptake of amatoxins. Silibinin is thought to reduce hepatic uptake and interrupt enterohepatic

circulation of amatoxins (8). Intravenous silibinin can be obtained in North America by calling the Madaus-sponsored hotline at (866) 520-4412. *N*-Acetylcysteine (NAC), traditionally used for the treatment of acetaminophen poisoning, may also be effective for nonspecific causes of hepatic injury. One comparative animal model demonstrated no benefit from NAC, penicillin, cimetidine, thioctic acid, or silymarin (9). When fulminant hepatic failure occurs, orthotopic liver transplantation is the only successful therapy (4,6).

Patients with coprine-containing mushroom ingestion should be counseled to avoid alcohol. Antihistamines may provide symptomatic relief.

Monomethylhydrazine-containing mushrooms (*Gyromitra* spp) may cause seizures. If benzodiazepine therapy is not immediately successful, the patient should be given IV vitamin B_6 (10). Gyromitrin causes an inhibition of glutamic acid decarboyxylase, similar to isoniazid, and B_6 is effective in this setting. Suggested doses are 1 g for children and 5 g for adults.

Muscarine-containing mushrooms (e.g., *Clitocybe* sp) will generally respond well to supportive care alone. Atropine may be used for severe cholinergic symptoms. Atropine dosing should be continued until reversal of pulmonary symptoms of bronchorrhea and bronchospasm.

Patients with hallucinations should be placed in a quiet, low-stimulus environment, if possible. Haloperidol or droperidol and lorazepam or another benzodiazepine can be used for severe agitation and hallucinations.

The treatment of rhabdomyolysis includes maintenance of urine output by infusion of IV fluids, consideration of urinary alkalinization, and possibly dialysis.

CRITICAL INTERVENTIONS

- Determine the time of onset of symptoms with respect to the time of ingestion.
- Consult a regional poison center, toxicologist, or mycologist to assist with mushroom identification and management.

- Administer IV fluids and antiemetics to patients with GI symptoms and dehydration.
- Admit patients with symptoms that begin 6 to 8 hours after ingestion and monitor for liver and renal dysfunction.

DISPOSITION

Patients who present with GI symptoms that begin within 2 hours after ingestion, have not had a mixed mushroom ingestion, and have low likelihood of *A. smithiana* ingestion may be considered for discharge after favorable response to IV fluids and oral challenge. Patients who have ingested hallucinogenic mushrooms may be safely discharged when their mental status returns to normal. Those who develop GI symptoms 6 to 8 hours after ingestion or whose ingestion is identified as a possible cyclopeptide-containing species should be admitted to the hospital, and liver and renal function should be followed. In the case of delayed presentation with hepatotoxicity from *A. phalloides* or other cyclopeptide-containing mushroom, consultation with a gastroenterologist and transfer to a transplant center is prudent.

Common Pitfalls

- Failure to include wild mushroom ingestion in the differential diagnosis of gastroenteritis, altered mental status, and liver or renal dysfunction of unknown cause.
- Assuming that a potentially lethal mushroom has not been ingested along with less toxic species because symptoms began soon after ingestion.
- Failure to appreciate that therapy is based primarily on clinical symptoms and should not be delayed or withheld until the mushroom is identified.

CHAPTER 355

Common Toxic Plants

Alicia B. Minns

There are nearly 50,000 calls to American poison centers every year regarding plant exposures (1). This represents about 2% of all calls. The majority of these exposures are accidental ingestions in children younger than 5 years of age. In the majority of calls, the type of plant is unknown. There are very few fatalities reported each year (1). The most serious poisonings typically involve adults who intentionally ingest the raw plant or tea made from the plant for perceived medicinal or hallucinogenic properties, or those who have mistaken the plant as edible. Plant identification can be very challenging. Plant chemistry is complex and most plants contain multiple chemicals and chemical classes that work independently or additively. Additionally, members of the same family of plants can have different toxic effects. A single plant may contain several different toxins. With exception of plants containing cardiac glycosides and anticholinergic plants, the treatment of plant toxicity is mainly supportive.

When evaluating a patient who presents to the emergency department (ED) with a possible plant exposure, identification of the plant should be attempted if possible. Communication with a poison center, medical toxicologist, or botanist is recommended, especially in a symptomatic patient. The most clinically important categories of plant toxicity are discussed below. For a more comprehensive list of plant toxicity, see Table 355.1.

TABLE 355.1
Toxic Principles

Toxin	Type of Toxin	Representative Plant	Toxic Part	Symptoms	Onset of Symptoms
Aconitum	Diterpene and norditerpene alkaloids	Delphinium, wolfbane, monkshood (*Aconitum* species)	Raw roots especially	Early, tingling or burning sensation in the fingers and toes, diaphoresis and chills, generalized paresthesias, numbness, a feeling of intense cold; later, severe vomiting, colicky diarrhea, skeletal muscle paralysis, cardiac rhythm disturbances, and intense pain	10–20 min
Anthroquinones	Anthraquinone glycosides	Aloe, cascara, senna, buckthorn	Probably all parts	Nausea, vomiting, diarrhea, abdominal cramps, palpitations; severe poisonings: nephrotoxicity, GI hemorrhage, seizures, dyspnea, fluid depletion; red color seen in alkaline urine, yellow-brown color in acidic urine can be seen	<6 hrs but no specific information
Anticholinergic	Belladona alkaloids varying with the individual plant: hyoscyamine, hyoscine, atropine, and scopolamine	Jimson weed, deadly nightshade, *Atropa belladonna*, henbane	All parts	Hyperthermia; dry, red, hot skin; dry mucus membranes; mydriasis; tachycardia; decreased GI motility; urinary retention; delirium; hallucinations; and coma in severe cases	Minutes to 2 hrs, varies with route of exposure
Aristolochic acid	Aristolochine	Asarum, snake root, colic root, Indian ginger	Herbal products especially	Acute: tachycardia, weak pulse, decreased heart tonus, constipation, polyuria, urogenital tract irritation, hepatitis; chronic: rapidly progressive fibrosing interstitial nephritis called "Chinese herb nephropathy" or "aristolochia herb nephropathy"	No information
Arnica	Helenalin, a sesquiterpene lactone	Arnica, leopard's bane, mountain daisy, mountain snuff, sneezewort	All parts (also found in herbal products and teas)	Vomiting, diarrhea, bleeding, CNS depression, muscle weakness, hypertension cardiotoxicity; uterine contractions may occur; allergic contact dermatitis	No information
Berberine	Berberine, a benzo-dioxoloquinolizine alkaloid	Barberry, jaundice berry, mahonia	Root and root bark (berries sour but edible)	Weak depressant action on heart and CNS causing hypotension, bradycardia, and vasodilation; acts as a weak local anesthetic; diarrhea, jaundice, dermatitis, stimulates bile production	No information
Calcium oxalates	Insoluble calcium oxalate crystals	Dieffenbachia, dumb cane, pothos, devil's ivy, philodendron, caladium	All parts	Drooling, irritation, stinging and pain of the mouth, tongue, throat; plants containing calcium oxalate crystals are not generally ingested in large enough quantities to produce a systemic intoxication	Immediate
Capsaicin	Oleoresin of capsicum (trans-8-methyl-*N*-vanillyl-6-nonen-amide)	Jalapeno peppers	Juice, pulp, seeds	Dermal irritation, erythema, burning pain, blisters, rash; GI effects; nasal and pulmonary irritant effects; coughing, bronchospasm	Rapid
Cardiac glycosides	Digoxin, digitoxin, other cardiac glycosides	Foxglove, oleander, yellow oleander, lily of the valley	All parts	GI effects seen early; bradycardia with AV block, hypotension, lethargy, dizziness seen later; seizures, electrolyte imbalances, hypertension, and coma are seen rarely; poisoning from acute accidental small-taste ingestions by children is rare	No information
Chinaberry	Meliatoxins A1, A2, B1, and B2 that are tetranorterpinoids of the liminoid class	Chinaberry (*Melia azedarach*)	Ripe fruit more toxic than unripe fruit, which is more toxic than other plant parts	Severe vomiting, diarrhea leading to dehydration and fluid-electrolyte depletion, nephrotoxicity, diaphoresis, pallor, lethargy, ataxia, respiratory failure, seizures, paralysis, coma	1 hr up to several hours
Cimicifuga	Triterpene alkaloids: actein, cimicifugoside, deoxyacetylacteol, and 27-deoxyactein	Black cohosh, black snakeroot, black root, bugbane, bugwort	Seeds, resin, extracts	Nausea and vomiting, dizziness, tremors, headaches, bradycardia or tachycardia; herbal preparations have been used as an abortifacient	No information
Colchicine	Colchicine alkaloids	Autumn crocus, naked lady, meadow saffron	All parts	Nausea, vomiting, diarrhea, abdominal pain, tachycardia, chest pain, later hypotension, bradycardia, seizures, bone marrow suppression, coagulopathy, ECG changes, and death	2–12 hrs

Toxin	Type of Toxin	Representative Plant	Toxic Part	Symptoms	Onset of Symptoms
Coniine	Piperidine alkaloids: coniine and gamma-coniceine with nicotine-like effects	Poison hemlock (*Conium maculatum*); fool's parsley (*Aethusa cynapium*)	Probably all parts	Vomiting, drooling, burning sensation in the throat, confusion, seizures, respiratory depression, tachycardia followed by bradycardia, intense muscle pain, muscle paralysis, rhabdomyolysis; CNS stimulation followed by CNS depression, respiratory paralysis, and death	No information but death may occur within 2 hrs
Cyanogenic glycoside	Amygdalin, the cyanogenic diglucoside D-mandelonitrile-β-D-gentiobioside	Hydrangeas, cotoneaster, braken fern, chewed pits of plum, apricot, bitter almonds, cherry, apple, pear, peach	Chewed pits and seeds from plums, apricots, bitter almonds, cherries, apples, pears, peaches	Nausea, vomiting, diarrhea, dyspnea, cyanosis, weakness, lightheadedness, excitation followed by seizures, stupor, disorientation, paralysis, weakness, coma, and cardiovascular collapse; poisoning from acute accidental ingestions is rare	1.5–2 hrs
Cytisine	Cytisine, a quinolizidine alkaloid which has action similar to nicotine	Wild indigo, Spanish broom, Kentucky coffee tree, golden chain tree	All parts	Profuse persistent vomiting, abdominal pain, hypotension, tachycardia, confusion, dyspnea, agitation, tremor, headache, fatigue, ataxia, drowsiness, headache, delirium, hallucinations, depressed spinal reflexes	15–60 min
Daphne	Mezerein and daphnetoxins are irritant diesters	Daphne, garland flower, flax olive	All parts; juice can be absorbed through broken skin to produce systemic symptoms	Burning, ulceration of throat, mouth, stomach, nausea, vomiting, bloody diarrhea, fluid and electrolyte imbalance, dermatitis, hematuria, albuminuria, weakness, coma, death; clinical picture similar to appendicitis	No information
Depressants	Various	Kava, valerian root, nicotine, hellebore, anticholinergics, monkshood, corn lily, death camus, mescal, rhododendron, golden chain	Depends on the plant	CNS depression: sedation, delirium, coma may be mild to severe, depending on the plant and the amount involved; depression may be one of other symptoms; hepatotoxicity may lead to CNS depression; usually large amounts are needed to produce severe CNS depressant effects	Rapid or delayed
Gelsemium	Indole alkaloids gelsemine, gelsemicine, sempervirine, and others.	Carolina jasmine, Caroline jessamine	All parts, contaminated honey	Headache, dry mouth, diaphoresis, mydriasis, difficulty speaking, muscle weakness, rigidity, seizures, dyspnea, bradycardia	No information
Grayanotoxin	Resinoid diterpenes	Azalea, rhododendron, mountain laurel	Nectar, flowers, leaves, and stems	Burning of the mouth, perioral numbness and tingling, nausea, vomiting, diaphoresis, hypotension, bradycardia, coma, altered level of consciousness, and seizures	30 min–2 hrs
Hellebore	Hellborin, a steroidal saponin (digitalis-like glycosides in some plants)	Hellebore, lenten rose, Easter rose, Christmas rose	Potentially all parts	Acrid taste, vomiting, colic, diarrhea, abdominal pain; dermatitis; kidney irritation; cardiac glycoside-containing plants can produce sinus bradycardia and escape beats; ingestion by pregnant women has resulted in abortion	No information
Hydroquinone	Hydroquinone	Bearberry, whortleberry, sandberry, uva-ursi	Leaves; no information on other plant parts	Vomiting and GI irritation, dermatitis, dizziness, headache, delirium, hepatotoxicity, hematuria with green or brown urine, respiratory failure, cardiovascular collapse, carcinogen	No information
Lobeline	Lobeline	Lobelia, cardinal flower, Indian tobacco, red lobelia, mordilla	Roots and seed pods are most toxic parts	Irritation of the mouth, nausea, vomiting, abdominal pain, bradycardia, transient tachypnea, hypertension, tremors, seizures, paralysis; with large doses, a curare-like paralysis can be seen; usually exposures occur from using lobelia as a smoking deterrent and not from plant ingestion	No information

Toxin	Type of Toxin	Representative Plant	Toxic Part	Symptoms	Onset of Symptoms
Nicotine	Nicotine alkaloids	Commercial tobacco, ornamental tobacco, wild tobacco	All parts	Violent vomiting, hypertension, and tachycardia followed by hypotension and bradycardia, seizures, hallucinations, muscle weakness, paralysis, respiratory failure	15–60 min
Oxalic acid (soluble oxalates)	Soluble oxalic acid and sodium, potassium, and ammonium oxalates	Rhubarb, sorrel, Virginia creeper, star fruit	All parts	Gastroenteritis, confusion, weakness, renal and liver damage, hypocalcemia, weak, irregular pulse, bradycardia, hypotension, and cardiac dysrhythmias, coma, seizures	2–12 hrs up to 48 hrs
Protoanemonine	Protoanemonin	Anemone, ranunculus, clematis	All parts, but highest concentrations seen in flowering stage	Acrid taste, burning sensation in mouth and throat; systemic symptoms are rare due to the bad taste and oral pain; abdominal pain, diarrhea, oral pain and ulceration, hematemesis, severe gastroenteritis may result from large ingestions; blisters and dermatitis	Usually rapid
Pyrethrum	Pyrethrum and the natural pyrethrins	Chrysanthemums, daisy, marguerites	Flower heads but possibly all parts	Allergic symptoms including sneezing, rhinitis, wheezing, dyspnea, scratchy throat, bronchospasm, dermatitis; numbness of lips, nausea, vomiting, tremors, headache, dizziness, paresthesia	10–60 min
Pyrrolizidine alkaloids	Various pyrrolizidine alkaloids depending on the plant species	Ragwort, groundsel, locoweed, crotalaria, trumpetweed, comfrey, senecio species; about 3% of ALL flowering plant species contain pyrrolizidine alkaloids	Mature leaves contain least concentration; contaminated honey and herbal teas are other sources	Veno-occlusive liver disease with vomiting, severe abdominal pain, hepatomegaly, right-upper-quadrant abdominal sensitivity, ascites; jaundice may or may not be seen; symptoms may be confused with Reye syndrome in children; onset may be delayed days to weeks after exposure; transplacental pyrrolizidine poisoning can occur	Delayed days to weeks
Solanine	A glycoalkaloid combination of an alkamine aglycone (solanidine) and a glycoside linkage to galactose, glucose, and rhamnose	Potato, tomato, eggplant (green parts), black nightshade	Green berries most toxic; leaves, shoots, ripe berries least toxic	Nausea, vomiting, headache, diarrhea, fever, mydriasis; mild hypotension, bradycardia, muscular cramping, increased salivation, paresthesias, and dyspnea are not common; anticholinergic symptoms can also be seen, leading to a confusing picture	2–24 hrs
Stimulants	Cicutoxin, thujone calycanthidine oenanthotoxin	Water hemlock, nux vomica, coriaria, Carolina moonseed	All parts should be considered toxic	Quick-onset seizures, drooling, vomiting, diarrhea, abdominal pain, tachycardia, hypothermia, mydriasis, muscle rigidity, acidosis, rhabdomyolysis, renal failure	5 min–1 to 2 hrs
Strychnine	Strychnine alkaloid and less-active brucine alkaloid	Strychnine tree, poison nut, quaker buttons, dog buttons, nux vomica	Seeds mainly, but all parts contain some toxin	A prodrome of muscle cramps (especially in the neck and back), stiffness, tightness, agitation; increased responsiveness to sensory stimulation may precede generalized muscle spasms; spasms and seizures are extremely painful and can be precipitated by any stimulation; patients can be awake and lucid during seizures; early deaths from respiratory failure and cardiac arrest; late deaths result from anoxic brain damage or multiple-organ failure due to hyperthermia	15 min
Tannins	An astringent that acts locally to precipitate proteins	Nutgall, oak, sumac	Raw acorns, young sprouts, and buds	Nausea, vomiting, abdominal pain, hepatotoxicity, and nephrotoxicity after large doses	No information
Toxalbumins	Toxalbumins consists of two approximately equal-size subunits (A and B) bound by disulfide linkage; structure similar to insulin, botulism, tetanus, cholera, and diphtheria	Castor bean, black locust, jequirity bean, Barbados nut	If seeds swallowed whole, minimal toxicity, but if seeds chewed or mashed thoroughly, severe symptoms may occur with only one seed	Severe GI irritation and possible lesions of the oropharynx, esophagus, or stomach with hemorrhage and sloughing of tissue; symptoms similar to an alkaline corrosive exposure; dehydration leading to fluid and electrolyte loss that can lead to shock; hepatotoxicity, nephrotoxicity, and CNS involvement can develop 2–5 d later allergic dermatitis	Usually within 2– 6 hrs but can be delayed 1–5 d

Toxin	Type of Toxin	Representative Plant	Toxic Part	Symptoms	Onset of Symptoms
Veratrum alkaloids	Zigadenus alkaloids, veratrum alkaloids, sabadilla—a veratrum-type alkaloid	Skunk cabbage, death camus, corn lily, false hellebore	All parts	Severe nausea, bitter taste, drooling, vomiting, diarrhea, diaphoresis, followed by bradycardia, syncope, dyspnea, paresthesias, weakness, hypotension, and ECG changes (sinus bradycardia, shortened PR interval, shortened QTc interval, bundle-branch block, nodal rhythm, depressed ST segment); animal teratogen	30 min–4 hrs
Vincristine Vinblastine	Vinca alkaloids: vincristine, vinblastine, and vindesine	Vinca, periwinkle, myrtle	All plant parts, plant usually smoked	Fever, nausea, and vomiting reported to occur within 24 hrs of an overdose; neuropathy, loss of deep tendon reflexes, delirium, hallucinations, coma, seizures, and death may occur the first week following exposure; severe bone marrow suppression, SIADH, paralytic ileus, alopecia	Within 24 hrs

AV, arteriovenous; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal.

CARDIAC GLYCOSIDES

Plants containing cardiac glycosides have been used medicinally for centuries as an emetic, abortifacient, antimalarial, in the treatment of heart disease, and in suicide (2). More than 200 naturally occurring cardiac glycosides have been identified to date, with *Nerium oleander* (common oleander) being responsible for the greatest number of toxic exposures each year. Other cardiac glycoside–containing plants include *Digitalis purpurea, Digitalis lanata* (foxglove), *Strophanthus gratus* (oubain), *Thevetia puruviana* (yellow oleander), *Convallaria majalis* (lily of the valley), and *Urginea indica* (squill). The seeds and the roots contain the highest percentage of cardiac glycosides, although all parts of the plant contain the toxin. Deliberate self-harm via ingestion of *T. peruviana* is a major problem in South Asia, where thousands of cases are reported each year with a case fatality rate between 4% and 10% (3).

Cardiac glycosides bind to and inactivate the Na^+/K^+ ATPase pump on the cytoplasmic membrane of the cardiac cell resulting in increased concentration of intracellular Na^+, and increased concentration of extracellular K^+ (3). The increased intracellular Na^+ concentration affects the Na^+/Ca^{2+} exchange, resulting in an increase in intracellular Ca^{2+}, ultimately leading to increased cardiac contractility and automaticity.

CLINICAL PRESENTATION

The toxic dose of a particular plant is difficult to determine and depends on factors such as the plant part ingested, the toxin concentration in the plant, age and heath of the patient, and the amount of toxin absorbed from the gut. Patients will usually develop symptoms within a few hours of ingestion, however time to clinical symptoms depends on how the plant was prepared. For example, a more rapid onset of poisoning occurs if the seeds are crushed compared to if the seeds are ingested whole.

After an acute ingestion, nearly all patients will have nausea and vomiting. The vomiting may be self-protective and limit the amount of toxin absorbed. Abdominal pain and diarrhea are also common. The main life-threatening clinical manifestation is cardiac toxicity. A wide range of cardiac conduction abnormalities and ECG abnormalities have been described such as sinus bradycardia, atrioventricular (AV) block, depressed ST segment, inverted T waves, and ventricular dysrhythmias such as bidirectional ventricular tachycardia. Refractory ventricular fibrillation and cardiogenic shock can occur in severely poisoned patients. Hyperkalemia is a marker of severe toxicity. Patients may have neurologic symptoms as well, such as tremor, drowsiness, ataxia, visual disturbances (yellow vision), and weakness (2–4).

Poisoning by natural occurring cardiac glycosides such as oleander is clinically indistinguishable from digoxin poisoning, however the toxicity from plant ingestion may last longer than the clinical effects seen with digoxin poisoning.

ED EVALUATION

An initial ECG to detect any rhythm disturbance, followed by continuous cardiac monitoring should be performed. Cross-reactivity of cardiac glycoside plants on digoxin immunoassay has been described but the digoxin level does not correlate with toxicity, so the test best serves as confirmation of the presence of cardiac glycosides. Serum chemistries should be checked and in an acute ingestion, hyperkalemia is a marker of more severe toxicity and associated with a worse outcome (4).

ED MANAGEMENT

Intravenous fluids should be given to treat the volume depletion that can occur from the gastrointestinal (GI) effects, as well as antiemetics to treat vomiting. The use of activated charcoal (AC) as a form of GI decontamination is controversial. The presence of nausea and vomiting in cardiac glycoside toxicity usually precludes the use of AC, however it can be considered in a patient with normal mental status who presents within 1 hour of ingestion without vomiting (adults: 50 to 100 g; pediatrics: 1 mg/kg). Use of digoxin-specific Fab antibody fragments, atropine, insulin/dextrose, sodium bicarbonate calcium, and pacing have been used successfully and are discussed in Chapter 325 How long a patient should be monitored depends on the patient's clinical status and some recommend cardiac monitoring for a minimum of 24 hours to monitor for delayed cardiac effects (4).

ANTICHOLINERGICS

Most plants with anticholinergic properties are from the family Solanaceae, and can be identified from their characteristic flowers. The Solanaceae family is extensively utilized by humans for food and medicine but is often rich in alkaloids that can cause life-threatening toxicity in humans. Plants that have anticholinergic properties include *Atropa belladonna* (deadly nightshade), *Mandragora officinarum* (mandrake), *Hyoscyamus niger* (henbane), *Datura,* and *Brugmansia* (2). *A. belladonna* contains berries that are particularly dangerous for children because they can be sweet. The alkaloids are generally distributed throughout the plant, so all ingested parts are toxic. Because the alkaloid concentrations vary with each plant and among parts of the plant, users are unaware of the amount of chemicals they are ingesting. Alkaloids in anticholinergic plants are also called tropane alkaloids and include atropine, hyoscyamine, and hyoscine (scopolamine). Tropane alkaloids are found in about 25 genera and 2,000 species of plants.

The tropane alkaloids competitively inhibit postsynaptic muscarinic receptors producing the classic anticholinergic syndrome (2). Since nicotinic cholinergic receptors are not affected, a more accurate characterization would be *antimuscarinic toxicity,* but

conventional literature most often uses the term “anticholinergic.” Some of the more commonly ingested plants are *Datura* species, known as Jimsonweed (*Datura stramonium*) and moonflowers (*Datura inoxia*), and *Brugmansia* species, generally known as Angel’s Trumpet. Jimsonweed seeds contain the highest concentration of tropane alkaloids, the equivalent of 0.1 mg of atropine per seed. The lethal dose of atropine is thought to be in the range of 10 mg. *D. inoxia* has the largest amount of scopolamine of any plant, with its leaves containing 3.85 mg/g. Scopolamine’s effects are similar to atropine and because it is also a tertiary amine, it can easily penetrate the central nervous system. In therapeutic doses, scopolamine antagonizes acetylcholine at muscarinic receptors; however, at high doses, it can also antagonize nicotinic receptors leading to flaccid paralysis. The lethal dose of scopolamine has been reported to be 2 to 4 mg (5). In previous case reports of patients who ingested either *D. inoxia* or *D. stramonium,* there were not significant differences in the clinical manifestations because both plants contain atropine, scopolamine, or both (5).

CLINICAL PRESENTATION

Various species contain different concentrations of tropane alkaloids; however, the clinical manifestations are usually similar. The onset of symptoms usually occurs within 1 to 4 hours of ingestion. If the plant is smoked or consumed as a tea, symptoms may occur more rapidly. The duration of effect may last from hours to weeks. Anticholinergic findings suggesting poisoning include hyperthermia, tachycardia, blurred vision, flushed dry skin, absent bowel sounds, urinary retention, agitation, hallucinations, lethargy, mumbling speech, undressing behavior (generally due to hyperthermia), and repetitive picking behavior. Blurred vision and photophobia may be due to mydriasis. Seizures and coma are reported in severe cases, but seizures may be a manifestation of hyperthermia. Anticholinergic effects delay gastric emptying, resulting in a prolonged duration of action. Patients may be amnestic to the events (2,5).

ED EVALUATION

Diagnosis is usually based on a history of exposure and the presence of typical features such as dilated pupils, flushed skin, and a rapid heartbeat. Positive identification of the plant should be attempted whenever possible, but identification of the plant is often difficult and common names often refer to more than one plant. Serum toxin levels are not available for most plant toxins but an ECG can detect plant-induced dysrhythmias.

ED MANAGEMENT

Treatment of anticholinergic plant exposure consists primarily of decontamination and supportive care. Mild cases of anticholinergic intoxication may be treated by discontinuing the offending agent alone. However, more serious cases may need to be hospitalized for more prolonged monitoring and observation. Activated charcoal is commonly administered despite the limited evidence of its efficacy. Supportive care is necessary to primarily maintain hydration and treat hyperthermia if present. Foley catheterization may be needed if bladder distension develops. Benzodiazepines can be used for agitation. Physostigmine is a carbamate that inhibits the enzyme cholinesterase and can be used for diagnosis and to treat symptoms (5). Management is discussed further in Chapter 344.

OXALATES

There are many plants that contain oxalates including common household plants such as *Dieffenbachia* spp (dumbcane), *Philodendron* spp (philodendron), *Spathiphyllium* spp (peace lily), and *Rheum rhabarbarum* (rhubarb). Plants containing oxalates are the most frequent class of toxic plants reported to poison centers (1). These plants contain calcium oxalate crystals (raphides) within specialized cells called idioblasts, which are released in response to mechanical pressure, such as chewing, leading to the clinical effects (6).

CLINICAL PRESENTATION

Upon ingestion of oxalate-containing plants, the needle-like oxalate crystals cause immediate pain, burning, and irritation to the lips, mouth, and throat. Swelling in the mouth and salivation may be

observed (7). Irritation in the GI tract manifests by nausea, vomiting, diarrhea, abdominal pain, and occasionally hematemesis (6). Most pediatric accidental exposures produce vomiting and diarrhea that resolve within a few hours. Although most exposures result in only minor symptoms, severe toxicity including airway compromise and renal failure from deposition of oxalate crystals has been reported (7). There are multiple other causes of oxalosis including primary oxalosis caused by genetic disorders, and secondary oxalosis from endogenous production, increased dietary intake, or increased absorption. Hyperoxaluria can also result from ethylene glycol ingestion, ingestion of high doses of vitamin C, or vitamin B6 deficiency (8).

ED EVALUATION

Symptomatic patients should receive a complete blood count, serum electrolytes including serum calcium and creatinine. A urinalysis to look for oxalate crystals may be obtained, although the presence of crystals is not specific to this ingestion. In a severe ingestion, oxalate-induced hypocalcaemia may occur and an ECG should be obtained. Patients should be monitored for facial and oral swelling that could lead to airway compromise.

ED MANAGEMENT

Decontamination is generally not needed following ingestion of oxalate-containing plants as most patients present with GI symptoms. Symptomatic treatment for oral irritation includes antihistamines, such as diphenhydramine. Intravenous fluids and antiemetics should be considered for patients with vomiting and diarrhea. Mild ingestions in patients who demonstrate clinical improvement in the ED may be discharged home. Any concern for airway compromise and/or renal dysfunction should prompt a longer observation period or admission to the hospital.

CICUTOXIN

The species of plants traditionally called water hemlock include *Cicuta* spp and *Oenanthe* spp. Water hemlock is also known as beaver

poison, children's bane, death-of-man, poison parsnip, and false parsley. Water hemlock plants are commonly mistaken for edible plants. They grow in swampy wet habitats and have roots that have been mistaken for wild carrots. Water hemlock plants are considered to be among the most toxic plants in North America and the United Kingdom (9). Similar to other poisonous plants, all components of the plant are toxic, however the tubers or roots are the most toxic portions of the plant. It smells like fresh turnips and tastes sweet. Case reports suggest that any amount ingested can lead to significant toxicity (9).

The main toxin in water hemlock, cicutoxin, is thought to be a noncompetitive gamma-aminobutyric acid (GABA) antagonist in the central nervous system. Blockade of the chloride channel on the GABA receptor allows for unopposed cellular depolarization that clinically causes seizures (9).

Water hemlock needs to be differentiated from poison hemlock, *Conium maculatum,* which was the poison Socrates was condemned to drink. *C. maculatum* resembles water hemlock and can also be found on banks of streams and rivers, however it has a purple-spotted stem and single tap root, and water hemlock has branched roots without purple spots (9). *C. maculatum* contains multiple different piperidine alkaloids including coniine and γ-coniceine, which act in a similar manner to nicotine. Their primary action is activation, then blockade, of nicotinic acetylcholine receptors, which are located throughout the body including brain, autonomic nervous system (sympathetic and parasympathetic), and neuromuscular junction. A variety of clinical effects can be observed including salivation, lacrimation, emesis, abdominal cramping, miosis, bradycardia or tachycardia, bronchospasm, and fasciculations. Severe poisoning results in weakness, seizures, coma, and paralysis. Coniine can cause rhabdomyolysis either by a direct effect on skeletal muscle or from producing convulsions. Although many symptoms of water hemlock and poison hemlock overlap, water hemlock causes seizures and potentially status epilepticus, and poison hemlock primarily causes respiratory paralysis (9).

CLINICAL PRESENTATION

The hallmark of water hemlock poisoning is recurrent, and occasionally refractory seizures. Mild toxicity results in nausea, vomiting, and abdominal pain within 15 to 90 minutes. In severe toxicity, salivation, diaphoresis, increased bronchial secretions, and respiratory distress develop soon after ingestion. Seizures and death resulting from status epilepticus soon follow (10). Seizures are typically grand-mal seizures which can lead to multisystem organ dysfunction including hyperthermia, rhabdomyolysis, lactic acidosis, acute kidney injury, and cerebral edema (10). Symptoms can persist for 24 to 96 hours after ingestion and many patients are amnestic to the events after ingestion. Death, if it were to ensue, usually occurs from respiratory failure secondary to seizures within 8 hours postingestion.

ED EVALUATION

The diagnosis of water hemlock poisoning is based on history and the presence of seizures. There is no routine test to confirm the presence of cicutoxin. Identification of the plant by a botanist or poison specialist is very helpful.

ED MANAGEMENT

There is limited utility for activated charcoal in this poisoning as vomiting and seizures are common clinical manifestations and put the patient at risk for aspiration. Treatment is mainly supportive with emphasis on stabilizing the airway and seizure control. Seizures should be treated aggressively with a benzodiazepine initially (e.g., in an adult lorazepam 4 to 8 mg, or diazepam 10 to 20 mg IV), and phenobarbital, 15 to 20 mg/kg IV loading dose, if seizures continue. Dosing should be titrated to effect. Phenytoin is most often ineffective in seizure control. Continuous EEG monitoring should be considered especially in patients who are intubated.

OTHER PLANTS

There are other plants which have a variety of other toxins and can cause symptoms, most often nausea and vomiting. These usually resolve spontaneously, or occasionally with minimal supportive care. Despite the number of ingestions, primarily by children, the case fatality rate is extremely low. Table 355.1 describes many of those toxins and plants.

CRITICAL INTERVENTIONS

- Obtain complete vital signs, including temperature, on all patients with suspected plant ingestions.
- Obtain an accurate name of the plant, including the common and scientific name.
- Evaluate patients with plant ingestions for possible upper airway obstruction.
- Provide supportive care as clinically necessary.

Common Pitfalls

- Failure to appreciate that plant poisoning can affect virtually any organ system.
- Failure to inquire about plant exposure and herbal use in patients with unexplained complaints, particularly GI and CNS symptoms and rashes.
- Failure to appreciate that different plants may have the same common name, which may include both toxic and nontoxic plant species.
- Failure to appreciate that some edible plants also have toxic components.
- Failure to appreciate that specific antidotes are available for the treatment of anticholinergic, cardiac glycoside, and cyanogenic glycoside plant poisoning.

CHAPTER 356

Dietary Supplements and Herbal Medications

Samara Soghoian and Lewis S. Nelson

In 1994, the Dietary Supplement and Health Education Act (DSHEA) (accessible online at http://www.fda.gov/Food/DietarySupplements) was enacted to amend the Federal Food, Drug, and Cosmetic Act with respect to dietary supplements. DSHEA defines dietary supplements as products other than tobacco that are intended to supplement the diet and that contain a vitamin, mineral, amino acid, herb, or other botanical, enzyme, or animal derivative such as glandular or organ tissues. Americans spend more than $28 billion on dietary supplements and they are consumed by more than 100 million Americans (1).

Dietary supplements may not be represented as conventional food items, but they are regulated as a special subcategory of food and not as medication. This distinction has important consequences for the types of evidence documenting safety and efficacy that are required of the manufacturers of dietary supplements. Unlike medications, dietary supplements need not be proven safe or effective prior to marketing, and most have never been studied in controlled trials.

Nevertheless, there is a common public misperception that dietary supplements are safe, in large part because they are “natural.” Yet the implication that they contain one or more active ingredients should logically raise concerns for the possibility of adverse effects. As with any pharmacologically active substance, the dose defines the poison and while low doses may be safe, high doses may lead to exaggerated or unexpected clinical effects.

Unlike the case of pharmaceuticals, if the US Food and Drug Administration (FDA) wants to restrict sale or use of a dietary supplement, it must prove that the product is dangerous (2). Unfortunately, no formal postmarketing safety-review mechanism exists, but if the FDA does find a product unsafe, it can warn the public, suggest changes in the formulation, urge the manufacturer to recall the product, recall the product, or ban it entirely. This last option has only been exercised once, when sales of ephedra-containing products were banned in light of hundreds of reported adverse events, including 10 deaths. The FDA has also issued warnings about hepatotoxicity from comfrey and kava, renal failure from products containing aristolochic acid, and the risk of stroke or myocardial infarction from tiratricol (thyroxine), the stimulant DMAA, or 1,3-dimethylamylamine, in geranium extract, and the presence of potentially dangerous anabolic steroids in vitamin supplements. Despite these dangers, none of these products have been removed from the market.

Assurance of quality control in the manufacture of dietary supplements falls under the Current Good Manufacturing Practices (CGMPs) standard. This requires that production be done under sanitary conditions and manufacturers have the responsibility to substantiate the safety of their products and to ensure the identity, purity, quality, strength, and composition of their ingredients. Unfortunately, the FDA has few resources available to enforce these standards.

Contamination of products is an important cause of toxicity from dietary supplements. In 1990, L-tryptophan was pulled from the US market when a Japanese brand was associated with more than 1,500 cases of eosinophilia myalgia syndrome (EMS), including 30 fatalities. It is believed that this epidemic was caused by inadvertent contamination with an impurity, 1,1′-ethylidenebis[tryptophan], also called EBT or “Peak E,” during the manufacturing process.

Herbal supplements may be particularly prone to contamination during the harvest and storage of wild plants. Investigation of two cases of cardiac glycoside exposure reported to the FDA in 1997 revealed that a bulk shipment of plantain imported from Germany

had been contaminated with *Digitalis lanata*. The contaminated plantain had been shipped to more than 150 manufacturers in the United States over a period of about 2 years before this was discovered and the products could be tested and recalled.

Misuse of herbal supplements may also be due to confusion between species with similar common names but very different pharmacologic properties. An epidemic of renal fibrosis occurred in Belgium in the 1990s when the manufacturers of a Chinese weight-loss supplement confused two products with similar common names and substituted the nephrotoxic *Aristolochia westlandi* (*guang fang ji*) for *Stephania tetandra* (*han fang ji*). Similarly, there have been multiple reported deaths from hepatic veno-occlusive disease after chronic use of teas from *Senecio longilobus,* a shrub containing hepatotoxic pyrrolizidine alkaloids. In Mexico, where "gordolobo" (big wolf) tea is used as an expectorant and anti-inflammatory, *Gnaphallium* species are generally implied. However, numerous plants are called by this name throughout Latin America, including the highly toxic *S. longilobus*.

A significant portion of both Chinese and Indian traditional remedies—more than 90% in one study—contain metals such as arsenic, lead, cadmium, copper, thallium, or mercury. This may not be inadvertent because therapy with metals has been an accepted part of these medical traditions and the inclusion of metals in patent medicines may be deliberate. Yet cases of heavy-metal toxicity have been clearly linked to such preparations.

Herbal preparations may also be adulterated with pharmaceutical medications. Chinese patent medicines have also been particularly implicated in this regard. Patent medicines are standard herbal preparations manufactured and sold in pill form. Analyses of Chinese patent medicines being sold internationally have estimated that between 7% and 24% of these products contain undeclared pharmaceutical medicines such as corticosteroids, ephedrine, benzodiazepines, and nonsteroidal anti-inflammatory drugs (NSAIDs). Numerous analyses of this type have been published (3). Drug–herb interactions are another source of adverse actions (Table 356.1) (4). For example, St. John wort is a potent inducer of

CYP3A4. Patients taking medications that are metabolized by this enzyme have decreased therapeutic effectiveness. Common medication classes include antiretrovirals, antidepressants, and antineoplastics (5).

TABLE 356.1
Dietary Supplement/Herb–Drug Interactions

Dietary Supplement/Herb	Drug	Interaction
Coenzyme Q	Warfarin	May reduce anticoagulant effect
Dong quai (*Angelica sinensis*)	Warfarin	May increase anticoagulant effect
Evening primrose oil	Warfarin	May increase anticoagulant effect
Garlic (*Allium sativum*)	Warfarin	May increase anticoagulant effect; should not be used with other anticoagulant drugs such as aspirin and other NSAIDs
Gingko (*Ginkgo biloba*)	Antiplatelet drugs	May increase effects
	MAOIs	May potentiate effect of MAOIs
Ginseng, American (*Panax quinquefolius*)	MAOIs	May cause headaches and manic episode
Ginseng, Chinese (*Panax ginseng*)	MAOIs	May cause headaches and manic episode
	Insulin	Hypoglycemic effects may be additive
	Stimulant drugs	May potentiate effect
	Warfarin	May decrease effectiveness
Glucosamine	Diabetes medicines	May increase insulin resistance
Kava Kava (*Piper methysticum*)	Sedative hypnotics	May potentiate effect
St. John wort (*Hypericum perforatum*)	HIV drugs, digoxin, blood thinners, chemotherapy agents, theophylline, SSRIs	May decrease effectiveness through CYP 450 induction Increased serotonergic effect
Valerian (*Valeriana officinalis*)	Alcohol and sedative hypnotics	Potentiates effects
Yohimbine	α_2-Blockers	Increased α_2-adrenergic blockade
	Tricyclics	Hypertension
	MAOIs	Additive effects

MAOI, monoamine oxidase inhibitor; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.
Reproduced with permission from the Report to the Chairman: Special Committee on Aging: U.S. Senate. *Health Products for Seniors: "Anti-Aging" Products Pose Potential for Physical and Economic Harm* (GAO-1–1129). Washington, DC: U.S. General Accounting Office, 2001.

A 1-year observational study in 14 US poison centers found that of 1,466 calls reporting ingestion of dietary supplements, 489 had symptoms that were likely to have been caused by the exposure. Of these, 31% (149 cases) were considered moderate to severe reactions, including 5 deaths (6). Although these numbers suggest that the adverse effects are uncommon, harm is well demonstrated. Given the undefined, but likely relatively small benefit of dietary supplements on improving human health, the risk–benefit relationship is highly unclear (7).

Much remains to be learned about the specific pharmacology, toxicology, and clinical utility of most dietary supplements (8). Very few supplements have been tested in randomized controlled trials. In 1991, the National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health (NIH) was

created with the explicit mission to explore complementary and alternative medicine in the context of rigorous science. Billions of dollars in grant monies have been disbursed through this program to fund all complementary health practices (including body manipulation and energetic healing techniques), and clinical trials of dietary supplements comprise only a small portion of this work. Recently, the result of the NCCAM-funded, highly controversial, and negative study of chelation therapy for heart disease called "Trial to Assess Chelation Therapy," or TACT, was published (9).

CLINICAL PRESENTATION

Dietary supplements form a category that is broadly unified in terms of intended use but not by any equivalence of biochemical composition or physiologic effect. Manifestations of toxicity are therefore varied. Acute effects may include allergy, any of the toxidromes, cardiac dysrhythmias, gastrointestinal distress, hepatitis, hepatic veno-occlusive disease, renal impairment, metabolic or electrolyte disturbance, hemorrhage, nervous system (CNS) stimulation or depression (see Table 356.2). Detailed information about specific agents and central potential interactions can be found at the NCCAM website (http://nccam.nih.gov). The Natural Medicines Comprehensive Database (http://www.naturaldatabase.com) is also a credible source of information.

TABLE 356.2
Toxic Manifestations of Selected Dietary Supplements by Presenting Complaint

Anticholinergic toxidrome: bittersweet (*Celastrus scandens*); burdock (*Arctium lappa*); deadly nightshade (*Atropa belladonna*); henbane (*Hyocyamus niger*); Jimsonweed (*Datura stramonium*); lobelia (*Lobelia inflata*); mandrake (*Mandragon officinarum*)

Bradycardia: cardioactive steroids: e.g., *Bufo* sp venom; dogbane (*Apocynum cannabimum*); foxglove (*Digitalis purpurea, D. lanata*); lily of the valley (*Convallaria majalis*); oleander (*Nerium oleander*); red squill (*Urginea maritima*)

Cardiac dysrhythmias (other): metals; monkshood (*Aconitum* species; "Caowu"), larkspur (*Delphinium* sp) [Na^+ channel activation]; quinine (*Chinchona* species) [Na^+ channel blockade]; see also "Stimulants"

Coagulopathy: danshen (*Salvia miltiorrhiza*); dong quai (*Angelica polymorpha*); garlic (*Allium sativum*); ginko (*Ginko biloboa*); tonka beans (*Dipteryx* sp)

Gastroenteritis: common: e.g., pokeweed (*Phytolacca americana*); senna (*Cassia angustifolia*); salmonella infection from rattlesnake meat; particularly concerning if due to metals

Hepatitis: borage (*Borago officinalis*); boron; chaparral (*Covillea tridentata, Larrea tridentata*); coltsfoot (*Tussilago farfara*); germander (*Teucrium chamaedrys*); kava kava (*Piper methysticum*)

Hepatic veno-occlusive disease: comfrey (*Symphytum officinale*); gordolobo (*Senecio* sp); heliotrope (*Crotalaria specatabilli; Heliotropium europaeum*); T'u-san-chi (*Gynura segetum*)

Hypotension: black cohosh (*Cimicifuga racemosa*); false hellebore (*Veratrum* sp); Hawthorn (*Craetaegus laevigata*); white cohosh (*Actea* sp)

Renal failure: aristolochic acid (*Aristolochia fangchi*); autumn crocus (*Colchicum autumnale*); colloidal silver; germanium (dioxide); juniper (*Juniper communis*), licorice (*Glycyrrhiza glabra*)

Peripheral neuropathy: clove oil (*Eugenia aromatic*); metals (arsenic, germanium, lead, mercury, thallium); podophyllum (*Podophyllum peltatum*); pyridoxine (B6); selenium

Sedative hypnotic: hawthorn (*Crataegus oxyacantha*); hops (*Humulus lupulus*); kava kava (*Piper methysticum*); valerian (*Valeriana* sp)

Seizures: camphor (*Cinnamomum camphora*); Chinese cucumber (*Compound Q*); fennel oil (*Foeniculum vulgare*); wormwood (*Artemesia absinthium*); see "Anticholinergics" and "Stimulants"

Stimulants: betel (*Areca catechu*); methylxanthines (cocoa [*Theobromo cacao*], coffee [*Coffee arabica*], tea [*Camellia sinensis*], kola [*Cola nitida/acuminata*], maté [*Ilex paraguariensis*], guarana [*Paullinia cupana*]); ephedra-like alkaloids (*Ephedra sinica;* ma huang; "herbal ecstasy"), ephedrone (khat [*Catha edulis*]), synephrine (bitter orange [*Citrus aurantium*]); nicotine (*Nicotiana tobacum*); nutmeg (*Myristica fragrans*)

DIFFERENTIAL DIAGNOSIS

The toxic effects of various herbal preparations are varied, and an appropriate differential diagnosis should be constructed with respect to these specific signs and symptoms. Conversely, because herbal preparations can affect every organ system, toxicity from dietary supplements should be considered in the differential diagnosis of any unexplained metabolic aberration or organ dysfunction. Inquiring about herbal and dietary supplements is the only way to increase the likelihood of considering these products as contributors to the patient's symptoms.

ED EVALUATION

The initial evaluation of a patient with potential toxicity from dietary supplements should proceed as for any other emergency department patient, with immediate attention given to the stabilization of the ABCs (airway, breathing, and circulation) and vital signs. A history of exposure to dietary supplements is clearly helpful in evaluating the potential for adverse effects but patients may not connect their symptoms with supplement use. Clinicians should be aware that many patients believe that dietary supplements are benign and may not include them on a list of "medications" unless explicitly prompted. Others may be hesitant to admit their use of herbals and

supplements to a physician for fear of censure or judgment. Clinicians should also be aware that products may be contaminated or that labeling may be unclear or misleading. Ultimately, the best gauge of toxicity is a focused history and physical examination in conjunction with selected ancillary tests of metabolic and organ-system dysfunction.

KEY TESTING

- Obtain sample of the product for potential testing by FDA or other analytical laboratory.
- Clinical testing is based on the patient's symptoms and findings on history and examination.
- In the uncommon patient with a suicide attempt using a dietary supplement, a serum acetaminophen concentration and pregnancy test, as appropriate, should be performed.

ED MANAGEMENT

The acute care of a patient with actual or potential toxicity from a dietary supplement is based on the nature and severity of illness. Gastrointestinal decontamination may be appropriate for patients who present early after a significant ingestion of a potentially toxic substance. Good supportive care is sufficient to treat most overdoses, but there are some notable exceptions. For example, poisoning with cardiac glycosides warrants therapy with multidose activated charcoal or digoxin-specific Fab fragments. Cyanide toxicity warrants specific therapy with sodium thiosulfate or hydroxocobalamin. Metal poisoning may require chelation therapy. Patients with anticholinergic toxicity may benefit from judicious use of physostigmine. All patients with possible adverse effects from a dietary supplement should be advised to discontinue its use. News about contaminated herbal and dietary products are in constant flux and all toxicity from herbals and dietary supplements should be discussed with the regional poison center who may help identify products that are contaminated, misrepresented, or pose significant

public health risks in addition to serving as an up-to-date informational resource for the clinician.

CRITICAL INTERVENTIONS

- Routinely ask about the use of dietary supplements while taking the medication history.
- Report all suspected drug interactions and adverse effects of dietary supplements by calling your regional poison center, or the FDA MedWatch program at 1–800-FDA-1088. (You may also report these online at http://www.fda.gov/Safety/MedWatch.)

DISPOSITION

Patient disposition depends on the presentation. Significant organ dysfunction demands admission to a higher level of care and a rigorous examination of all potential causes. Patients who take intentional overdoses should have psychiatric evaluation prior to discharge.

Common Pitfalls

- Failure to recognize that most people regard herbals and dietary supplements as benign and may not alert the clinician to their use unless specifically prompted.
- Failure to consider toxicity from herbals and dietary supplements in the differential diagnosis of unexplained organ dysfunction.
- Failure to contact knowledgeable resources for up-to-date trends on contaminated products.
- Failure to warn patients of potential interactions between medications and herbals and dietary supplements.

CHAPTER 357 Seafood Toxins

Brenna M. Farmer

Seafood has been a dietary staple, safely eaten for thousands of years. However, occasional poisoning from seafood can result in many clinical syndromes, which mainly involve the gastrointestinal (GI) or neurologic systems, and with the popularity of world travel and importation of seafood, seafood toxin–related syndromes may be encountered anywhere. For emergency physicians, understanding the diagnosis and treatment of these syndromes is essential.

Ciguatera poisoning follows ingestion of large carnivorous fish containing high concentrations of ciguatoxin, which is produced primarily by the dinoflagellate, *Gambierdiscus toxicus*. *G. toxicus* is found in tropical and subtropical waters along coral reefs. Ciguatoxin is a colorless, tasteless, heat- and acid-stable, lipid-soluble polyether that bioaccumulates in the organs (particularly, the liver and gonads) of predator fish (1). Outbreaks typically occur in the Caribbean, Australia, and the South Pacific but have been reported worldwide, with more than 400 species of fish, mostly reef fish, implicated. Barracuda, grouper, red snapper, amberjack, eel, sea bass, and Spanish mackerel are most commonly involved. Fish larger than 2 kg are more likely to be contaminated with significant quantities of toxin. Ciguatoxin acts to open sodium channels, which increases sodium permeability through voltage-gated sodium channels (1).

Scombroid poisoning occurs with ingestion of fish containing histamine, also known as scombrotoxin (1). Bacteria under the scales of the fish convert histidine, a normal component of fish muscle, into histamine when the fish is poorly stored or improperly

refrigerated. The bacteria are commonly found on the surface of dark or red-fleshed fish of the Scombroidae family (tunas, skipjack, bonito, and mackerels) and other fish with dark flesh, such as dolphin fish (mahi mahi), bluefish, amberjack (yellowtail), herring, sardines, and anchovies. Scombrotoxin is heat-stable and can sometimes impart a metallic or peppery taste (1). Patients taking isoniazid or MAOI, inhibitors of diamine oxidase, are more sensitive to scombrotoxin. The histamine content of spoiled flesh can vary considerably throughout a fish, being highest near the gut cavity. Individual sensitivity to scombroid poisoning also varies considerably; females are thought to be more susceptible.

Tetrodotoxin is a heat-stable, water-soluble neurotoxin found in the skin and viscera of puffer fish (saltwater and freshwater varieties), porcupine fish, sunfish, toadfish, the blue-ringed octopus, some species of salamanders, and *Atelopid* frogs. Puffer fish, the most common source of tetrodotoxin, is eaten as the delicacy *fugu* in some Asian countries. Although tetrodotoxin is concentrated in the fish's skin and internal organs, it can be found in all parts of the fish. Most poisonings still occur in Japan, where sushi chefs must be licensed in the proper technique of preparing puffer fish to minimize risk of death with improper preparation. Tetrodotoxin is a sodium-channel inhibitor and reduces neuronal conduction (1,2). Tetrodotoxin bioaccumulates in the liver and gonads of the puffer fish like ciguatera (1).

Paralytic shellfish poisoning results from the ingestion of bivalve and gastropod mollusks (mussels, clams, oysters, scallops, and cockles) and occasionally some univalve mollusks, starfish, crustaceans, and fish (including puffer fish, which are more commonly associated with tetrodotoxin). These creatures become toxic when dinoflagellates, especially *Gonyaulax* spp., multiply explosively, causing red tides. Red tides are visible marine overgrowths of phytoplankton and dinoflagellates. Ingestion of filter-feeding shellfish from regions with red tides can lead to epidemic poisonings, such as paralytic shellfish poisoning. Toxic shellfish are commonly found in the cold, temperate waters of the Americas, the western coast of Europe, and the coastal waters of

Japan but are increasingly reported in warmer climates. Outbreaks have occurred in Nova Scotia, New Brunswick, Maine, and Alaska (3). The toxins do not harm shellfish but are concentrated in viscera and can take several weeks to be eliminated. Seabirds, several fish species, and mammals are susceptible to poisoning. Saxitoxin, a potent, heat-stable, water-soluble neurotoxin of paralytic shellfish poisoning, acts by blockading fast sodium channels in nerve and muscle during depolarization, and results in a conduction block that principally affects motor neurons and muscle (1). There is no reliable taste, smell, or color to identify contaminated shellfish.

Another seafood toxin–associated illness seen with red tides is neurotoxic shellfish poisoning, which also results in a ciguatera-like syndrome but is generally less severe. It is caused by brevetoxins from *Ptychodiscus brevis,* a dinoflagellate found off the coast of southeastern North America and Western Europe during algae blooms. The toxins are accumulated by clams and oysters. Brevetoxin opens sodium channels similarly to ciguatoxin (1).

A third shellfish poisoning, amnestic shellfish poisoning, a toxic encephalopathy, is caused by ingestion of shellfish, mainly mussels, containing domoic acid (1). The largest outbreak was in Prince Edward Island, Canada. The heat-stable toxin is derived from *Nitzschia pungens,* another dinoflagellate that causes red tides. Domoic acid acts as an excitatory neurotransmitter at the glutamate receptor (4).

Diarrheic shellfish poisoning can occur after ingestion of mussels, *Dinophysis* spp., containing okadaic acid and dinophysistoxins. Outbreaks have been reported in the Netherlands, Japan, Europe, and most recently in Greece (1,5). Okadaic acid and dinophysistoxins are lipophilic, fat-soluble, and inhibit essential protein phosphatases (1).

A syndrome similar to diarrheic shellfish poisoning occurs with ingestion of azaspiracid-contaminated mussels, *Mytilus edulis.* Outbreaks have occurred in the Netherlands and Ireland. Azaspiracid is a lipophilic, highly oxygenated polyether found in *Protoperidinium* spp., another dinoflagellate (6).

Another poorly understood seafood toxic syndrome is hallucinatory fish poisoning, ichthyoallyeinotoxism. It is reported around the world, particularly in areas near the Indian and Pacific Oceans and the Mediterranean Sea. The sea bream, *Sarpa salpa,* related to the porgie is implicated in carrying an unknown toxin responsible for this type of seafood poisoning (7).

CLINICAL PRESENTATION

Seafood toxin poisoning typically affects the GI and neurologic systems.

Ciguatera poisoning typically occurs 2 to 30 hours after ingestion of ciguatoxic fish. Patients characteristically present with circumoral and/or extremity paresthesias, arthralgias, myalgias, diarrhea, vomiting, bradycardia, and pruritus. A classic, though uncommon, finding is hot–cold temperature sensation reversal in which a burning or painful sensation is associated with touching cold objects (8). Patients may present initially with only neurologic symptoms; which may be delayed up to 72 hours after ingestion or may occur without GI symptoms. Hypotension is common and may be due to fluid loss, bradycardia, peripheral vasodilatation, or myocardial depression. Symptoms vary among different patients and depend on where the fish were caught and what parts were eaten. More severe toxicity, especially hypotension and bradycardia, occurs in patients who have been previously poisoned by ciguatera. Other common neurologic symptoms include asthenia, paresis, tremors, and pain affecting the joints, head, and abdomen. The paresthesias do not conform to dermatomal or peripheral nerve distribution. A sensation of looseness of the teeth is another unusual symptom. Insomnia, neurosis, depression, and hallucinations may occur. Other features include dyspnea, diaphoresis, salivation, tearing, chills, neck stiffness, pruritus, rashes, and tachycardia. In pregnant patients, violent fetal movements have been described. Less commonly, transient blindness, convulsions, rhabdomyolysis, polymyositis, or paralysis may occur. Death, although uncommon, may result from severe dehydration or cardiac or respiratory failure (8).

The onset of scombroid poisoning is normally within 1 hour of ingestion. The presentation is similar to, but generally less severe than, IgE-mediated allergic (anaphylactic) or anaphylactoid reactions. Patients experience intense flushing of the upper trunk and face, nausea, vomiting, hives, pruritus, tachycardia, bronchospasm, and occasionally hypotension. Severe reactions, such as bronchospasm, hypotension, and supraventricular tachyarrhythmias, are more likely to occur in patients with pre-existing cardiac or respiratory disease. Findings usually resolve within 6 to 12 hours from the time of ingestion.

Patients with *tetrodotoxin poisoning* usually present within 10 to 45 minutes after ingesting the toxic seafood. However, case presentations delayed up to 20 hours are reported. Early symptoms include a feeling of exhilaration. Four stages of poisoning have been described. Initially, circumoral paresthesias, salivation, nausea, and vomiting occur, followed by peripheral paresthesias and numbness. Sensory symptoms then become more generalized, with ascending paralysis of the extremities, although deep-tendon reflexes remain intact. In the third stage, ataxia and paralysis of peripheral and bulbar muscles occur. Finally, respiratory muscles are affected, although patients may still be conscious. Patients may become unconscious and completely paralyzed, with dilated nonreactive pupils and loss of all brainstem reflexes. Because of its effect on the sodium channel, cardiac arrhythmias, including A-V blocks, are also reported (2). Recovery occurs over a period of days and, unless complicated by anoxia, is complete. Death is usually due to paralysis of the respiratory muscles.

Paralytic shellfish poisoning occurs within minutes of ingestion and usually begins with neurologic symptoms including perioral, hand, and finger paresthesias, with associated nausea and abdominal pain. These are followed by paresthesias of the face and extremities and progressive muscle paralysis. Bulbar muscles are often affected, causing dysarthria, dysphagia, diplopia, and loss of the gag reflex. Other features include vertigo, ataxia, transient blindness, altered temperature perception, hypotension, headache, and low back pain. The paresthesias then become generalized, and a

progressive paralysis including loss of deep-tendon reflexes and fixed-dilated pupils develops. Respiratory paralysis may be fatal without rapid intervention. Complete recovery typically occurs within 24 to 48 hours (3).

Neurotoxic shellfish poisoning causes a syndrome similar to ciguatera. Circumoral paresthesias that generalize, headache, tachycardia, and muscle cramps are common. Nausea, abdominal pain, vomiting, and diarrhea also occur. Seizures and coma have occurred with severe poisonings.

Amnestic shellfish poisoning also produces neurologic and GI findings, with onset of effects from minutes to 38 hours. Abdominal pain, nausea, and diarrhea, with loss of memory, severe headache, confusion, and disorientation commonly occur. Severe intoxication can result in seizures and coma. Improvement occurs 24 hours to 12 weeks after ingestion of mussels containing domoic acid (4).

The main symptoms from *diarrheic shellfish poisoning* and *azaspiracid poisoning* are GI. Onset occurs from 30 minutes to 10 hours after ingestion of seafood (5), and the predominant effects are diarrhea, nausea, vomiting, abdominal cramps, and chills. Patients usually do not have a fever (5,6). Full recovery from this self-limited illness occurs within 3 to 4 days (1).

Ichthyoallyeinotoxism, *hallucinatory fish poisoning,* begins within minutes to 2 hours of ingestion of toxic fish. Initial symptoms resemble ethanol intoxication and include ataxia, incoordination, and general malaise/weakness. Within hours, patients report hallucinations (visual and/or auditory) and become delirious. Nightmares can occur. Some patients experience less common symptoms of vomiting and diarrhea. Symptoms usually resolve within 24 to 36 hours, although weakness can persist for days (7).

DIFFERENTIAL DIAGNOSIS

Patients who present with illness related to seafood toxins generally have a predominance of GI and neurologic signs and symptoms. The clinical presentations of ciguatera, neurotoxic shellfish, tetrodotoxin, and paralytic shellfish poisoning may be difficult to distinguish, as

all may involve symptoms of paresthesias, weakness, and ataxia. Geographic location, predominant symptoms, and the type of fish eaten are used to determine the specific etiology. A common shellfish origin has been found for toxins associated with tetrodotoxin and paralytic shellfish poisoning.

Infectious viral and bacterial gastroenteritis must also be considered in any patient presenting with GI complaints. Common seafood pathogens include hepatitis A, Norwalk virus, and *Vibrio* spp. (including *V. cholerae, V. parahaemolyticus,* and *V. vulnificus*).

Encephalitis, meningitis, Guillain–Barre, botulism, and transient ischemic attack, or stroke, should be considered in patients presenting with paralysis or other neurologic findings. In patients presenting with seizures, electrolyte and metabolic abnormalities, other toxins or an underlying seizure disorder should also be considered.

Anaphylaxis to seafood should be considered, especially in patients with signs and symptoms of scombroid poisoning. A metallic or strong peppery taste to the fish and the type of fish may distinguish scombroid from a true allergic reaction. Skin flushing can occur with scombroid poisoning but also with red man syndrome, niacin ingestion, monosodium glutamate ingestion, and ethanol–disulfiram interactions.

ED EVALUATION

One should obtain a history of foods ingested in patients with the combination of GI and neurologic symptoms. Special attention should be paid to the type of seafood ingested, locale, time of ingestion, and onset of symptoms. The origin of the seafood should be identified if possible, as this may help to differentiate poisonings specific to certain regions. Public health officials may be able to assist in this process and provide information about similar cases or known quarantined fishing areas.

Physical examination should focus on vital signs, respiratory function, and the neurologic examination, including deep-tendon

reflexes and sensation. Patients with tachycardia or hypotension should be evaluated for hypovolemia.

KEY TESTING

- Fingerstick glucose: To assess for cause of altered mental status
- Electrolytes: To exclude nontoxin-related neurologic problems, or disturbances due to vomiting and diarrhea
- Forced vital capacity/negative inspiratory force: To assess for severity of neuromuscular involvement or impending respiratory failure in patients with severe neurologic involvement
- Seafood toxin assay: To assess for toxin in the seafood (if any food is available)

ED MANAGEMENT

Supportive care is the mainstay of therapy in all seafood toxin–related syndromes. Airway, breathing, and circulation (ABCs) should be addressed initially. Patients should have intravenous access and cardiac monitoring as appropriate. In patients with abnormal ventilation as demonstrated by decreased vital capacity, negative inspiratory force, or hypopnea or apnea, intubation and mechanical ventilation should be considered. Abnormal heart rhythms such as bradycardia should be addressed (see Chapter 84, Bradydysrhythmias). Patients with tachycardia or hypotension should initially receive intravenous saline, but vasopressors such as dopamine, norepinephrine, or phenylephrine may be required if hypotension is unresponsive to saline.

In patients who may still have seafood in their stomach, activated charcoal (1 g/kg) should be considered. Antiemetics should be used for nausea and vomiting.

Specific therapy has been used in *ciguatera poisoning.* Although there are conflicting data on its efficacy, *mannitol,* 1 g/kg, is often recommended for patients with severe neurologic toxicity such as coma (9,10). Amitriptyline, which may act by blocking sodium channels, usually provides some relief from the chronic neurologic symptoms of ciguatera poisoning. Other agents used with varying

degrees of success include fluoxetine, nifedipine, vitamins B_{12} and C, calcium gluconate (1 to 3 g intravenously over 24 hours), lidocaine, and tocainide. Two patients who were treated with gabapentin (400 mg orally three times daily) experienced a rapid improvement and recurrence of symptoms after therapy was discontinued. Other medications commonly used for neuropathic pain have been used for persistent paresthesias. Indomethacin and cyproheptadine are commonly used to relieve arthralgia and pruritus, respectively.

For *scombroid poisoning,* treatment includes H_1- and H_2-receptor antagonists. H_2-blockers such as cimetidine appear more effective than type 1 blockers such as diphenhydramine (3). Epinephrine may benefit the rare severely ill patient with hypotension who is not responsive to intravenous saline or with bronchospasm not responsive to albuterol. Corticosteroids are of little benefit, as this poisoning is due to histamine only (i.e., no secondary mediators such as leukotrienes are released). Once stabilized, patients with scombroid poisoning can be discharged on oral antihistamines for 48 hours.

Benzodiazepines are useful to manage the disturbing hallucinations and nightmares experienced by patients with *hallucinatory fish poisoning.* Edrophonium and neostigmine have been used to reverse motor paralysis due to tetrodotoxin poisoning but have not been studied in controlled trials.

Besides supportive care, prevention is the best treatment of all. Fish weighing >2 kg or of those types known to be frequently affected should be avoided to prevent ciguatera. Patients should also avoid eating specific organs in which the toxins accumulate, such as the liver and gonads for ciguatera and tetrodotoxin. The government bans the sale of certain fish known to carry the toxin. In Miami, barracuda is banned from sale due to the risk of ciguatera poisoning. The local health department also periodically tests shellfish for certain toxins and when red tides occur, and quarantines are instituted as appropriate.

CRITICAL INTERVENTIONS

- Assess ABCs and evaluate pulmonary function early with measurements of forced vital capacity and negative inspiratory force.
- Provide supportive care, including antiemetics for nausea and vomiting and intravenous saline for dehydration and hypotension.
- Treat scombroid poisoning with H_1- and H_2-receptor antagonists.
- Consult a regional poison center and/or public health officials for current treatment advice and to report outbreaks.

DISPOSITION

Most patients may be discharged home after evaluation and supportive treatment in the emergency department. Outpatient follow-up should be arranged. Patients with abnormal vital signs, neurologic symptoms, persistent vomiting, or inability to tolerate oral fluids should be admitted to the hospital. Patients with neurologic symptoms or those at risk for development of respiratory weakness or paralysis should be admitted to an intensive care unit for close monitoring. Local or state departments of health should be notified of all cases of suspected seafood poisoning, as timely intervention may prevent additional exposures.

Common Pitfalls

- Failure to consider seafood poisonings in patients with gastroenteritis and/or neurologic symptoms.
- Failure to admit patients with neurologic findings for monitoring.
- Failure to treat scombroid poisoning with antihistamines.

SECTION XXIV
Environmental Emergencies

Section Editor: LOUIS J. LING

PART 1 • PHYSICAL EXPOSURE INJURIES

CHAPTER 358
Hypothermia

Eric W. Ling and Danielle E. Hart

Hypothermia is defined as a core body temperature $<35^{\circ}C$. It is further classified into mild (32° to 35°C), moderate (28° to 32°C), and severe ($<28^{\circ}C$) hypothermia.

CLINICAL PRESENTATION

Many organ systems are significantly impacted by low body temperature. The clinical presentation varies with the degree of hypothermia (Table 358.1) but may be as subtle as confusion or disorientation.

TABLE 358.1
Effect of Temperature

	Mild (32°–35°C, 89.6°–95°F)	Moderate (28°–32°C, 82.4°–89.6°F)	Severe (<28°C, <82.4°F)
Cardiovascular		Bradycardia, conduction delay, AV block	Bradycardia, hypotension, AV block
	Tachycardia, elevated BP	Atrial arrhythmias, Osborn waves	Ventricular and atrial arrhythmias, asystole
	Increased CO, Increased SVR	Decreased CO, increased SVR	Paradoxical vasodilatation, decreased CO
Respiratory	Tachypnea, decreased minute volume	Hypoventilation, loss of airway reflexes, risk of aspiration	Progressive hypoventilation, apnea
	Bronchospasm and bronchorrhea	Decreased O_2 consumption and CO_2 production, respiratory acidosis	ARDS, pulmonary edema
			Respiratory acidosis
Neurological	Apathy, disorientation, confusion, amnesia	Paradoxical undressing, hallucinations	Loss of cerebral autoregulation, decreased CBF and cerebral metabolism
	Shivering, increased muscular tone	Decreased shivering, joint rigidity	Shivering lost, muscle rigidity, areflexia
	Ataxia, dysarthria, lack of coordination	Sluggish pupils, hyporeflexia, decreased LOC	Fixed and dilated pupils, unresponsiveness, no neurologic signs of life
Hematologic	Early inhibition of clotting factors	Hemoconcentration, hypovolemia, increased vascular permeability	Coagulopathy, DIC
		Hypocoagulable or hypercoagulable state	Bleeding diathesis, thrombocytopenia
Renal/Metabolic	Cold-induced diuresis, increased metabolism	Decreased renal blood flow and GFR, decreased metabolism	Oliguria, possible renal failure, rhabdomyolysis
	Hypokalemia	Hyperglycemia, hyperkalemia	Hyperglycemia, hyperkalemia
	Metabolic and respiratory alkalosis	Metabolic acidosis	Metabolic and respiratory acidosis
Gastrointestinal	Ileus, decreased GI absorption, Bowel wall edema	Hepatic insufficiency, pancreatitis, gastric erosions	Hepatic insufficiency, lactic acidosis

A general guiding principle is that no patient is dead unless he or she is warm and dead. Aggressive resuscitation should, therefore, be provided to almost all hypothermic patients, as traditional markers of death, including loss of brainstem reflexes with fixed and dilated pupils, rigor mortis, and dependent lividity, do not preclude a survivable condition. There are few exceptions to this, such as when there are clearly nonsurvivable traumatic injuries or the chest wall is frozen and incompressible. If there is any doubt, rewarming should be initiated (1). Severe acidosis, hyperkalemia, hyperammonemia, and hypofibrinogenemia may be poor prognostic indicators (2,3), but they should not be used in isolation to determine potential survivability. Survival has been reported with an initial pH of 6.51 or an initial potassium of 11.8 mEq/L. Likewise, temperature on arrival or seemingly nonsurvivable circumstances are not indications to withhold aggressive rewarming. Complete neurologic recovery has been observed with presenting temperatures of 14.2°C (57.5°F) in a child and 13.7°C (56.7°F) in an adult. A patient survived after therapeutic hypothermia at 9°C (48.2°F), and the longest reported period of cold water submersion with good neurologic recovery is 66 minutes. Patients in whom hypothermia and its neuroprotective effects occur rapidly and prior to cardiovascular collapse have the most favorable prognoses. Death can be declared when the patient's core temperature has been higher than 32°C (89.6°F) for 30 minutes (1).

DIFFERENTIAL DIAGNOSIS

The diagnosis of hypothermia is unequivocally established by core temperature measurement. However, the events leading to thermoregulatory failure and hypothermia vary widely causing overlap of the traditional definitions of primary hypothermia solely due to overwhelming environmental cold stress and secondary hypothermia due to cold stress complicated by impaired thermoregulation. In both primary and secondary hypothermia, patients tend to have circumstances that preclude an appropriate adaptive behavioral response to cold such as insufficient shelter or clothing, wilderness activities, substance intoxication, and medical or

traumatic co-morbidities. Evaluating and addressing these precipitating factors is an essential component of ED management to prevent recurrence and treat underlying illness. Secondary hypothermia frequently has a worse prognosis due to an increased resistance to rewarming and organ dysfunction from underlying illness. Causes of secondary hypothermia and thermoregulatory impairment are listed in Table 358.2 (4).

TABLE 358.2
Causes of Secondary Hypothermia

- Extremes of age
- Sepsis
- Multiple trauma
- Malnutrition
- Central nervous system
  - Cerebrovascular accident
  - Traumatic brain injury
  - Intracranial infection
  - Intracranial mass lesion
  - Hypothalamic dysfunction
    - Wernicke
    - Anorexia
  - Spinal cord injury
- Peripheral nervous system
  - Autonomic dysfunction
  - Peripheral neuropathy
- Endocrine system
  - Hypothyroidism
  - Hypoadrenalism
  - Hypopituitarism
  - Ketoacidosis
  - Hypoglycemia
- Dermatologic system
  - Burns
  - Desquamative skin conditions
- Pharmacologic influences
  - Opiates
  - Benzodiazepines
  - Barbiturates
  - Phenothiazines
  - Tricyclic antidepressants
  - Alpha blockers
  - Ethanol use
- Iatrogenic causes
  - Exposure during resuscitation
  - General anesthesia
  - Therapeutic cooling
- Psychiatric disease

ED EVALUATION

The initial evaluation focuses on the degree of hypothermia, cardiovascular stability, and searching for any precipitating factors.

As standard thermometers do not read below 34°C (93.2°F), special equipment is required for the accurate measurement of low body temperatures. The pulmonary artery temperature is considered "gold standard" (5); however, this is impractical in an ED setting and undesirable in a hypothermic patient with an irritable myocardium. Esophageal probes approximate myocardial temperatures (1) but should be placed in the lower esophagus (45 cm from nares in adults) to avoid inaccurate measurements from inspired gases in the trachea. Bladder temperatures reasonably estimate core temperature (5) and are well tolerated but may be inaccurate during warm water peritoneal lavage. Rectal temperatures can be accurate, though readings may lag during rewarming due to cold feces in the rectal vault (1,5,6). Tympanic membrane temperatures obtained by a thermistor or a thermocouple placed in direct contact with the tympanic membrane are accurate, but the placement and maintenance of such devices is difficult in an emergent resuscitative setting (5). Infrared devices which measure the temperature in the external auditory canal do not have sufficient accuracy or precision (7). Skin, oral, or axillary temperatures do not accurately reflect core temperatures and should not be used when hypothermia is suspected. Of the monitoring devices commonly available, esophageal probes appear to best approximate core temperature in static or dynamic situations and do not have the lag time seen with rectal, and to a lesser extent, bladder probes (5). If body cavity lavage is employed for rewarming, the temperature probe should be placed at a distant site.

It can be difficult to palpate a pulse in the hypothermic, bradycardic, and hypotensive patient. Some authors feel that a narrow-complex organized rhythm, even without palpable pulses, is a contraindication to cardiopulmonary resuscitation (CPR) due to concern over precipitating ventricular fibrillation. However, it seems most reasonable, and in keeping with American and European guidelines, to apply the same criteria to hypothermic patients as

normothermic patients: if there is no pulse after careful assessment for 1 minute, CPR should be performed concurrently with the initiation of rewarming procedures (7–10). Cardiac ultrasound or auscultating pulses with Doppler ultrasound can assist in this evaluation and inform decisions about the necessity of CPR (11).

Many physiologic functions are altered at low temperatures (see Table 358.1). A bedside glucose test should be obtained early. Hypoglycemia may represent underlying pathology or exhaustion of glycogen stores by shivering and should be corrected. Hyperglycemia and hypokalemia are common and frequently resolve spontaneously during rewarming. Laboratory studies include a blood gas, lactate, electrolytes, magnesium, calcium, and phosphorus levels, complete blood count, PT, aPTT, INR, fibrinogen, renal function tests, liver function tests, lipase, urinalysis, creatine kinase, and cardiac enzymes. Blood and urine cultures, toxicology screen, blood alcohol level, cortisol level, thyroid function tests, and pituitary function tests may also be considered depending on the clinical scenario. Blood gas values should not be corrected for temperature when determining resuscitation treatment (1,12,13). Although this is an inaccurate representation of in vivo pH and pCO_2, it best represents the appropriate intracellular–extracellular pH gradient from the influences of temperature fluctuations on the pH and should guide treatment toward the goal of an uncorrected pH of 7.40 and an uncorrected pCO_2 of 40, as acid–base disturbances predispose to ventricular arrhythmias (7,12,14).

An electrocardiogram (ECG) and a chest x-ray should be obtained (14). ECG Osborn waves (also known as J waves) can be seen and bradycardia is expected below 32°C (89.6°F) (Fig. 358.1), whereas atrial and ventricular arrhythmias are frequent with core temperatures below 30°C (86°F). Although hyperkalemia may be present, typical ECG findings are often masked by hypothermia. Appropriate imaging for traumatic injuries should follow rewarming. Patients with persistent altered mental status after rewarming should have a head CT to evaluate for contributing intracranial pathology.

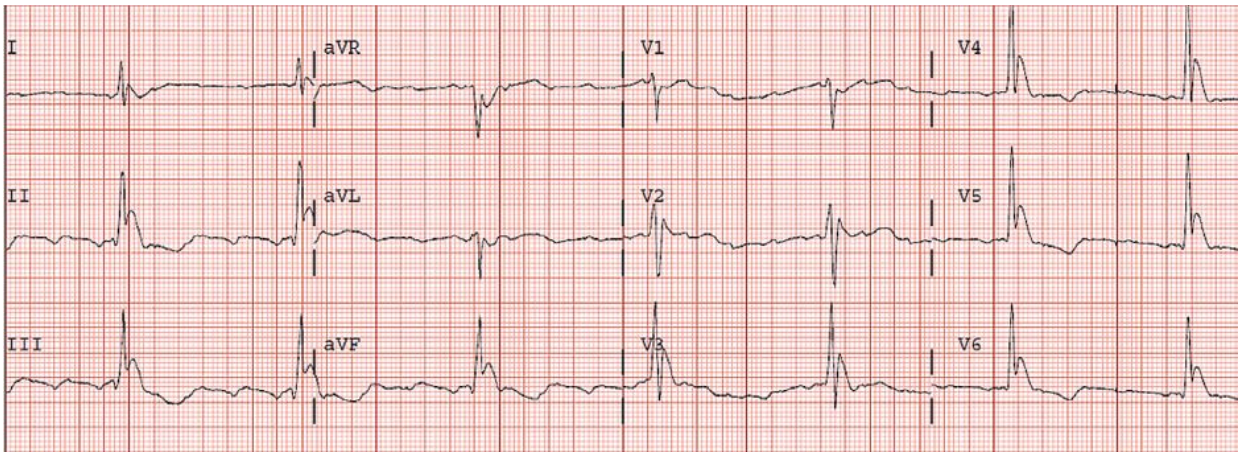

FIGURE 358.1 ECG in hypothermia: prominent Osborn wave in the QRS complex. Arrhythmias are common. This case demonstrates slow atrial flutter in 3:1 block.

Dysfunction of the coagulation system begins as the temperature drops below 35°C (95°F) and alters coagulation enzyme kinetics. Thrombocytopenia, platelet dysfunction, platelet sequestration, and prolongation of the PT and aPTT are frequently noted (4,14). Since standard laboratory equipment automatically heats samples to 37°C (98.6°F), in vitro measurements often underestimate in vivo coagulopathy (4). Rewarming generally reverses the coagulopathy and, with the exception of major trauma, replacement of platelets and coagulation factors is often unnecessary (4,14).

KEY TESTING

- Core temperature with an appropriate low-reading temperature probe
- ECG
- Blood glucose
- Initial laboratory studies: Blood gas, lactate, electrolytes, complete blood count, creatine kinase, urinalysis, coagulation studies, cardiac enzymes
- With failure to rewarm or with no clear environmental etiology: thyroid function tests, cortisol level, blood and urine cultures, head CT or brain MRI, toxicology screen, pituitary function tests

ED MANAGEMENT

As with other critically ill patients, management begins with the airway, breathing, and circulation (ABCs). If protective airway reflexes are absent or respiratory failure is present, endotracheal intubation is necessary and confers a low risk of precipitating ventricular arrhythmias (1,15). When neuromuscular blockade is required, duration will be extended due to globally slowed metabolism, and cold-induced masseter spasm may persist despite paralytics (7). Therefore, some authors recommend avoiding paralytics below 30˚C (86˚F) (11). If spasm interferes with orotracheal intubation, a jaw spreader may be useful and alternative techniques including nasotracheal intubation or cricothyrotomy should be considered (11).

Asystole, the natural culmination of severe hypothermia, and ventricular fibrillation from concomitant metabolic derangements or physical manipulation, becomes increasingly likely below 28˚C (82.4˚F) (14). CPR should be initiated if a central pulse cannot be palpated within 1 minute or if there is no organized cardiac activity on ultrasound. Given the possibility of prolonged CPR (hours) and a stiff chest wall, mechanical compression devices (Lucas, LifeStat, AutoPulse, etc.) may provide superior CPR. Placement of internal jugular or subclavian central venous catheters, transvenous pacing catheters, and rough handling of the patient can disturb an irritable myocardium and should be avoided when possible in favor of transcutaneous pacing and femoral central venous catheters. Although ventricular arrhythmias are most concerning, atrial fibrillation and sinus bradycardia are more common.

The treatment of arrhythmias in hypothermia is controversial. Perfusing stable arrhythmias typically resolve with rewarming and do not require specific treatment. However, unstable or nonperfusing arrhythmias may benefit from treatment. Optimizing the cardiac environment is essential for all unstable arrhythmias, best obtained by working toward an uncorrected pH of 7.40 with sodium bicarbonate and ventilator parameters. The few studies using amiodarone have yielded conflicting results (16,17), whereas lidocaine appears to be safe but of limited efficacy (1,7). Atropine is

frequently ineffective in hypothermic bradycardia and, traditionally, vasopressors were also thought to be ineffective below 30°C while conferring a risk of toxic accumulation due to delayed metabolism. However, recent animal data have found that vasopressors (epinephrine and vasopressin) increase the rate of return of spontaneous circulation when compared with controls while anti-arrhythmics (amiodarone and bretylium) appear to have no effect (16). The American Heart Association's guidelines allow vasopressor administration and defibrillation per usual ACLS protocols while recognizing the paucity of data (8). In contrast, the European Resuscitation Council continues to recommend withholding vasopressors until temperature rises above 30°C and doubling the time between administrations until the temperature exceeds 35°C (9). With these guidelines and limited data, it would seem reasonable to administer epinephrine and/or vasopressin during resuscitation less frequently and in fewer total doses while below 30°C. Alternatively, a single dose of vasopressor prior to warming above 30°C may reduce the risk of vasopressor-related toxicity during rewarming while preserving some of the benefits. Intramuscular or subcutaneous medications are not recommended due to prolonged and erratic absorption with severe peripheral vasoconstriction.

Although data are limited, conventional teaching limits cardioversion attempts to one shock in patients with cardiopulmonary arrest below 30°C (86°F). In contrast, some authors recommend subsequent attempts for every increase in temperature of 1° to 2°C (11). Defibrillation should be initiated per ACLS protocols once the temperature is >30°C. Given the lack of established efficacy, neither defibrillation nor vasopressor administration should delay rapid rewarming efforts in an arrested patient below 30°C. In a few case reports, transcutaneous pacing has successfully treated bradycardia with hypotension, but as bradycardia and hypotension may be physiologic and reflect decreased tissue oxygen utilization, the clinical utility of transcutaneous pacing remains uncertain (18).

Once a patient is stabilized, causes of secondary hypothermia should be considered and, if identified, treated (7). Empiric antibiotics in hypothermic neonates, elderly, and

immunocompromised patients are widely accepted, as an underlying infection is common (14). If there is an inadequate response to rewarming, empiric steroids and/or levothyroxine should be considered for potential adrenal failure or myxedema coma (7).

Core afterdrop and *rewarming shock* are important concepts in rewarming. *Core afterdrop* is the continued decline in core body temperature during the initial phases of rewarming as cooled blood from the extremities returns to the core circulation (7,10). Although of greatest theoretical concern with active external rewarming, its clinical significance is unclear. *Rewarming shock,* conversely, is a complex phenomenon with greater clinical significance (10). Vasodilation, returning metabolic products, and acidemia from rewarming peripheral tissues may manifest as an unforeseen decline in blood pressure, decrease in cardiac output, or cardiopulmonary arrest.

Rewarming methods (Table 358.3) are classified as passive external rewarming, active external rewarming, simple active core rewarming, and invasive active core rewarming. The optimal rewarming method depends on the degree of hypothermia, cardiovascular stability, and available resources. Multiple rewarming modalities are frequently utilized simultaneously.

TABLE 358.3
Warming Method

Method of Rewarming			Rate of Temperature Increase
Passive Rewarming			
Indications: Previously healthy patient with mild primary hypothermia			
	Blankets, dry environment, cover head		0.5°–2°C per hour, reliant upon shivering
Active External Rewarming			
Indications: Mild to moderate hypothermia without cardiovascular instability			
	Radiant heating		Not well reported, likely clinically insignificant
	Electric heating blankets		0.3°–0.8°C per hour
	Forced air (BairHugger, etc.)		0.8°–2.4°C per hour
	Plumbed blankets (Arctic Sun, etc.)		2.5° –3.0°C per hour
	Warm water immersion		2°–4°C per hour
Active Simple Core Rewarming			
Indications: Any degree of hypothermia			
	Warmed IV fluids with heated and humidified oxygen		0°–2°C per hour, frequently clinically insignificant
Active Invasive Core Rewarming			
Indications: Moderate to severe hypothermia, cardiovascular instability, or cardiopulmonary arrest			
	Body cavity lavage		
		Stomach	Minimal, clinically insignificant
		Bladder	Minimal, clinically insignificant
		Colon	Minimal, clinically insignificant
		Peritoneum	1°–4°C per hour
		Hemithorax, closed	1°–6°C per hour
		Open mediastinal irrigation[a]	8°C per hour
	Endovascular warming (Alsius, etc.)	Femoral catheter	1°–3°C per hour
	Extracorporeal circulation	Hemodialysis/hemofiltration (HD/HF)	1°–3°C per hour
		Continuous arteriovenous rewarming (CAVR)	3°–4.5°C per hour
		Continuous venovenous rewarming (CVVR)	1.5°–4.7°C per hour
		Cardiopulmonary bypass (CPB)	6.9°–9.8°C per hour

[a]For cardiopulmonary arrest only.

Passive external rewarming is effective in mild primary hypothermia (7), essentially minimizing further heat loss and enabling the patient to generate heat shivering by placing the patient in a warm, dry environment, removing all wet garments, insulating the head and body, and providing sufficient calories to sustain shivering.

Active rewarming measures are recommended for core body temperatures $<32^{\circ}C$, cardiovascular instability, suspicion of a secondary cause of hypothermia, impaired thermogenesis, multiple trauma, chemically induced or central nervous system–induced vasodilatation, or failure of passive rewarming methods (7).

Active external rewarming is used for mild to moderate hypothermia without cardiovascular instability and includes any technique that places the patient in direct contact with a heat source (7). Despite theoretical concerns regarding core afterdrop due to rapid peripheral warming, studies investigating forced air rewarming (BairHugger, Mistral-Air, WarmAir, etc.) have not observed clinically significant

core afterdrop (19). Recent literature suggests that circulating water-filled garment systems (Arctic Sun, ThermoWrap, CoolBlue, etc.) may be more effective than forced air rewarming and can approach cavity lavage rewarming rates (20,21). Many devices used for therapeutic hypothermia can be repurposed for rewarming accidental hypothermic patients. Immersion in warm water is effective but creates difficulty with monitoring and resuscitation while diathermy, the transfer of heat by ultrasonic or low-frequency microwave radiation, has been studied but is not clinically available (7). Caution must be applied with any rewarming mechanism involving direct conduction, since vasoconstricted skin is easily burned (7).

Simple active core rewarming, in combination with other techniques, is appropriate for any degree of hypothermia. Intravenous rehydration is frequently required as cold-induced diuresis and vascular permeability deplete and hemoconcentrate the intravascular space. Heated intravenous fluids (40° to 42°C) and warmed, humidified inspired oxygen (40° to 45°C) help prevent further heat loss but are inadequate for rewarming (2,7,22). Use of a high-flow countercurrent (Level 1) fluid infuser allows the heating and infusion of both crystalloid and blood products. Commercial fluid warmers or a microwave oven are alternative options for heating fluids; however, neither dextrose-containing solutions nor blood should be warmed in a microwave (4,7).

Invasive active core rewarming should be employed swiftly in cardiopulmonary arrest, cardiovascular instability, and severe hypothermia <28°C. Body cavity lavage is performed with sterile fluid heated to 39° to 45°C. Lavage of the stomach, colon, and bladder can be used as adjunctive measures, but small surface areas limit rewarming when these techniques are used in isolation (2,4,7). Peritoneal lavage with a technique similar to diagnostic peritoneal lavage (DPL) is more effective (2,3,22), whereas closed thoracic lavage is the most effective. In thoracic lavage, large-bore chest tubes are inserted both anteriorly and posteriorly, preferentially in the right chest due to theoretical concerns with irritating the heart in the left chest. Thoracic lavage rewarming rates begin around 2° to 3°C per hour (2,22), with rates up to 6°C per hour with a high-flow

countercurrent infuser (7). Adequate drainage through the posterior thoracostomy must be ensured to avoid an iatrogenic tension hydrothorax (7). Open mediastinal irrigation through a thoracotomy incision is effective in hypothermic patients with cardiopulmonary arrest, with rewarming rates up to 8°C per hour (2,3,7).

Endovascular devices are frequently used to induce therapeutic hypothermia (Alsius, InnerCool, etc.). Off label, these devices can also rapidly rewarm patients at an hourly rate of 1° to 3°C using femoral access (23). Case reports suggest that endovascular or plumbed blanket devices designed for therapeutic hypothermia may achieve rates equal to body cavity lavage and are less traumatic.

Extracorporeal methods have been successful in the resuscitation of both moderate and severe hypothermia. Hemodialysis and hemofiltration provide the benefits of eliminating toxic substances but have slower rewarming rates than other extracorporeal methods. Continuous arteriovenous rewarming offers faster rewarming rates but, since there is no external pump mechanism, requires a systolic blood pressure of at least 60 mm Hg to drive the flow. For the placement of 8.5 French arterial and venous catheters, either percutaneous or cutdown techniques can be utilized, with lines generally placed at contralateral femoral sites. The catheters' size mandates that the patient weigh at least 40 kg (7). Continuous venovenous rewarming may offer another option, but require a dedicated pump and are not generally available in the ED (22).

Cardiopulmonary bypass (CPB) provides complete circulatory support with extracorporeal oxygenation, and is the optimal method of rewarming patients in cardiac arrest (2,3,7). Some authors recommend CPB for all core body temperatures <25°C regardless of perfusing cardiac activity, and in patients with frozen extremities CPB may result in less tissue loss. Medical centers without CPB capability face a difficult choice in whether to attempt rewarming or to transfer severely hypothermic patients to a CPB facility for optimal therapy. This decision should be informed by the availability of CPB at the receiving facility, estimated time of transit, and cardiovascular stability.

There is conflicting evidence regarding the optimal rate of rewarming and the goal temperature of rewarming. Some studies have shown that hemodynamically stable patients with moderate to severe hypothermia experience good outcomes after rewarming with minimally invasive techniques (24), and there is currently no evidence that rapid rewarming of a patient with a perfusing rhythm improves outcome (7). However, rewarming times longer than 12 hours are associated with poor outcomes (7), and prolonged hypothermia can be associated with depressed cardiac function after rewarming (25). Regarding goal temperature, some authors recommend that hypothermic patients with cardiac arrest be warmed only to a therapeutic hypothermic state and thereafter follow therapeutic hypothermia protocols. There is insufficient evidence to make firm recommendations regarding therapeutic hypothermia after arrest or the rate of rewarming in hemodynamically stable patient with severe hypothermia (24).

CRITICAL INTERVENTIONS

- Use an appropriate low-reading temperature probe to make the diagnosis of mild, moderate, or severe hypothermia
- Use active core rewarming for severe hypothermia, cardiovascular instability, or cardiopulmonary arrest
  - external rewarming can be used in uncomplicated mild to moderate hypothermia
- Identify and treat causes of secondary hypothermia
- Monitor and correct acid–base status to prevent arrhythmias
- Rewarming must be continued to a core temperature of at least 32°C for 30 minutes before survivability can be determined

DISPOSITION

Disposition depends on the degree of hypothermia and the available resources at the presenting hospital. Healthy individuals with mild primary hypothermia may be discharged after rewarming. Patients with moderate or severe hypothermia, cardiovascular instability, secondary hypothermia, appreciable frostbite, or significant

comorbidities should be admitted for further evaluation and management. If the patient requires transfer to another facility, available rewarming strategies should be employed as swiftly as possible without significantly delaying transport. If there is consideration of cardiopulmonary bypass, early notification of the receiving facility is critical.

Common Pitfalls

- Failure to recognize hypothermia in elderly patients with altered mental status.
- Failure to adequately assess circulatory status prior to the initiation of CPR.
- Failure to appreciate that survivable hypothermic patients can nonetheless appear clinically dead.
- Failure to appreciate the limited efficacy of many medications at low core temperatures ($<30^{\circ}C$) and the potential for significant delayed toxicity upon rewarming.
- Failure to recognize that dysrhythmias and cardiopulmonary arrest are frequently resistant to conventional ACLS treatments until core temperature rises above 30°C.
- Failure to appreciate that mechanical irritation of the myocardium with central line placement, chest tube placement, or rough handling of the patient can result in ventricular fibrillation.

CHAPTER 359

Cold-Induced Tissue Injuries

Joseph M. Weber and Scott C. Sherman

While retreating from Moscow in the winter of 1812 to 1813, Napoleon's surgeon general, Baron Dominique-Jean Larrey, recognized the ill effects of the freeze–thaw–freeze cycle when he witnessed soldiers thawing their feet by campfires at night, only to march again in the cold the next day. He proposed that the limbs should be rewarmed slowly by rubbing them with wet snow, which then became the accepted practice for more than a century. In the 1930s and 1940s, research described the benefits of rapid rewarming. In the 1960s, Mills popularized what has become the cornerstone of treatment today—warm the frozen limb in a 40° to 42°C water bath, avoid additional trauma, and use whirlpool baths to debride necrotic tissue (1).

Today, as a result of better availability of shelters among the homeless, improved patient awareness, and better protective clothing, the number of cases of frostbite has decreased. Immersion foot, however, is still common, especially among the homeless (2). These injuries can occur in any climate. Recreational inhalation of nitrous oxide and fluorinated hydrocarbons have caused frostbite to the face and cold-induced swelling that can compromise the airway (3,4). Another example is frostbite resulting from the inappropriate application of ice packs (5). As tissue temperatures drop to 10°C, cutaneous sensation is lost, and capillary blood flow decreases. With temperatures from 3° to 11°C, cutaneous capillary blood flow is reduced by 60%, and 5- to 10-minute cycles of vasodilatation and

vasoconstriction begin to occur to both preserve core temperatures and provide blood flow to the extremity. When core temperatures are threatened, however, blood flow to the extremity becomes negligible, and skin temperatures may drop as much as 0.5°C per minute.

In frostbite, ice crystals form in the extracellular space at tissue temperatures below 0°C. Frostbite requires ambient temperatures of −6° to −15°C, as radiation of heat from deeper tissues maintains surface temperatures somewhat above the environment. Irreversible tissue damage begins when extracellular ice crystal formation draws water from intracellular spaces by osmosis, causing intracellular dehydration and enzymatic disruption. With further cooling or rapid freezing (10°C per minute), intracellular ice crystals cause further cellular damage. The vascular endothelium and nerve tissues are more sensitive to cold than muscle, bone, and cartilage and are the first to be injured.

On rewarming, reperfusion creates an environment of progressive microvascular ischemia. This secondary insult is the result of multiple factors. Fluid extravasates through previously damaged endothelium. The interstitial fluid is rich in inflammatory mediators (prostaglandin and thromboxane) that promote vasoconstriction and platelet and leukocyte aggregation. Edema formation and endothelial injury may arrest capillary and arteriolar blood flow. Blister formation occurs secondary to vascular injury. Clear blisters form from extracellular exudation of fluid. Hemorrhagic blisters occur when deeper subdermal vessels are disrupted, indicating more severe tissue injury. The end result is arterial thrombosis, ischemia, and ultimately necrosis.

Nonfreezing cold-induced tissue injury has many similarities to frostbite. *Frostnip* is a reversible superficial ice crystal formation and intense vasoconstriction without tissue destruction. The tissue changes of *chilblains* result from vascular inflammation and tissue hypoxia secondary to cold-induced vasoconstriction. With *immersion foot,* the tissues are saturated with water so that the thick stratum corneum of the soles and feet becomes swollen, thickened, and fragmented. There is variable edema of the upper dermis. An

inflammatory response ensues, influenced by the water itself in most cases, not a concomitant fungal or bacterial process. The thinner stratum corneum of the dorsum of the foot does not absorb as much water and, therefore, is less likely to be involved. With exposure to much colder water, there is an added insult of vasospasm, intravascular thrombosis, and damage to nerve, fat, and muscle. Thus, the threshold for developing immersion foot is decreased in cold environments. Cold water causes injury in <48 hours versus up to 72 hours in warmer conditions.

The development of frostbite depends on more than ambient temperature. Duration of exposure, wind chill, humidity, and wet skin (and clothing) all increase the likelihood of frostbite. Other predisposing factors include alcohol consumption, psychiatric illness, vehicular failure, and drug abuse (6). Longer duration of exposure worsens outcome and is more predictive of injury than the ambient temperature alone (7).

CLINICAL PRESENTATION

Cold-induced tissue injuries present in various forms—*frostnip, chilblains, immersion foot, and frostbite*. Frostnip is the mildest form and presents with numbness, pain, pallor, and paresthesias to the affected extremity. The distal extremities—fingers, toes, ears, and nose—are most commonly involved. Frostnip usually resolves within 30 minutes, so persistent symptoms suggest a more serious diagnosis.

Chilblains usually occurs in patients with an underlying vasculitis after repeated exposure to dry, above-freezing cold temperatures. Patients present with erythema, edema, pruritus, and a burning sensation. Rarely, ulcerations, vesicles, and bullae may form. The lesions may have a purple or blue appearance. Commonly affected areas include the hands, feet, and pretibial areas. Manifestations occur 12 to 24 hours after cold exposure. The condition is recurrent in some individuals with repeated exposures, and this form is often bilateral and symmetric.

Immersion foot (also known as *trench foot*) can occur at any temperature but is more severe when wet exposure is combined with a cold environment. Although a wet environment is a prerequisite, perspiration and absorbent socks may be all that is required. Immersion foot usually develops slowly over hours to days. Immersion foot is the most commonly encountered cold-induced injury and occurs frequently in the homeless. Numbness and pain are common and may be so severe that the patient is unable to walk. The affected foot is cool, erythematous, and edematous (2). The distinction between immersion foot and the post-thaw phase of frostbite may be difficult and, therefore, a detailed history is essential.

Frostbite, like frostnip, commonly occurs on the digits, nose, and ear. Initially, the frozen tissue is mottled and violaceous. As rewarming occurs, the tissue becomes hyperemic, and the initially insensate extremity regains some sensation. After rewarming, frostbite can be classified into superficial (first- and second-degree) and deep (third- and fourth-degree) injury (Table 359.1).

TABLE 359.1
Classification of Frostbite Severity

Severity	Symptoms
First-degree: partial thickness	
Erythema, edema, hyperemia	Stinging, burning
No blisters or necrosis	Possible throbbing and aching
Occasional skin desquamation (5–10 d later)	Possible hyperhidrosis
Second-degree: full thickness	
Erythema, significant edema	Numbness
Clear vesicles	
Blisters may desquamate and form blackened eschar	
Third-degree: involves subcutaneous tissue	
Violaceous/hemorrhagic blisters due to injury to the reticular dermis and subdermal plexus	Initially insensate; later, shooting pains, burning, throbbing, aching
Skin necrosis	
Blue-gray skin	
Fourth-degree: involves muscle, tendon, and bone	
Little edema	Possible joint discomfort
Initially mottled, deep red, or cyanotic	
Later dry, black, mummified	

Adapted from Britt L, Dascombe W, Rodriguez A. New horizons in management of hypothermia and frostbite injury. *Surg Clin North Am.* 1991;71:345–370.

The appearance of first-degree frostbite is of a pale, white epidermis with surrounding erythema. Second-degree frostbite is heralded by clear blister formation with surrounding erythema and edema (Fig. 359.1), whereas third-degree frostbite consists of hemorrhagic blister formation, indicating deeper tissue injury. Fourth-degree frostbite consists of deeper necrosis and tissue loss (Fig. 359.2). Caution must be exercised, however, as this classification system does not always provide an accurate prognosis, nor does it alter initial management. Poor prognostic indicators include hemorrhagic blisters, nonblanching cyanosis, and hard, nondeforming skin (indicating loss of dermal viability). Positive prognostic signs include maintenance of pinprick sensation, normal skin color, and large clear blisters (7). In general, patients with

superficial frostbite will recover with little or no tissue loss, and patients with deep injury will ultimately have tissue necrosis.

FIGURE 359.1 Second-degree frostbite (partial thickness). Notice the clear blisters. (Photo credit: Scott Sherman, MD.)

FIGURE 359.2 Chronic demarcated fourth-degree frostbite with necrosis of the toes. (Photo credit: Scott Sherman, MD.)

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of frostbite includes the other causes of cold-induced injury—frostnip, immersion foot, and chilblains. Other diseases that can appear similar include peripheral vascular disease, cellulitis, and dermatologic conditions such as stasis dermatitis, erysipelas, and bullous diseases but can be differentiated by history. Trauma to an extremity or compartment syndrome may mimic or coexist with a cold-induced injury. Chemical or thermal burns should also be considered if an accurate history cannot be obtained.

ED EVALUATION

Initial evaluation begins with a survey of the patient for systemic hypothermia (see Chapter 358) and major trauma. Treatment of either of these conditions supersedes care of a frostbitten limb. A

detailed history includes exposure temperature and duration, wind conditions, and moisture. A history of thawing in the field and refreezing should be documented as it portends a poorer prognosis. A previous history of frostbite doubles the patient's risk for recurrent cold-induced tissue injury in the same location (8). A history of psychiatric illness or alcohol and drug use is common in patients with frostbite. Finally, other risk factors such as peripheral vascular disease, diabetes, and smoking should be ascertained.

Physical examination begins with a core temperature and trauma primary and secondary surveys followed by a thorough examination and description of any frostbitten areas. A neurologic and vascular examination should include pulses (by Doppler if necessary), capillary refill, motor exam, and two-point discrimination. Wound description should include skin color and temperature, blister formation and color (clear or hemorrhagic), and soft-tissue consistency.

Laboratory studies are not helpful in the initial evaluation of the frostbitten patient. They may be helpful in patients with concomitant illness or associated conditions, such as rhabdomyolysis. Radiographic evaluation is limited to evaluation for trauma.

KEY TESTING

- Most patients do not need testing
- Testing and imaging for associated conditions such as hypothermia, rhabdomyolysis, and trauma

ED MANAGEMENT

Prehospital care should focus on avoiding mechanical trauma and refreezing injury. A frostbitten extremity should not be rewarmed in the field if there is a risk of refreezing before reaching definitive care. A victim who must walk through snow should do so before thawing frostbitten feet. Rubbing the frozen extremity with a warm hand or snow, once thought to be beneficial, does not augment blood flow and causes increased tissue damage (7). In the

emergency department (ED), general management of any cold-injured patient includes removal of wet clothing and complete exposure. Treatment begins by addressing hypothermia and dehydration.

Thereafter, therapy should be directed to the patient's specific type of tissue injury. Frostnip usually resolves spontaneously with dry rewarming in ambient temperatures, and no further therapy is necessary. Management of chilblains is also supportive. The affected skin should be rewarmed, washed, dried, and dressed in dry, soft, sterile bandages. Elevation is important to minimize edema that can predispose to infection (7). Nifedipine improves symptoms and helps prevent recurrences in patients with repeated exacerbations. A dose of 20 mg three times a day is recommended as tolerated by its effect on blood pressure (9). Prazosin has been effective for both acute exacerbations and prophylaxis. Patients should avoid further exposure to cold temperatures.

Treatment of immersion foot is supportive, consisting of bed rest, elevation of the legs, and air-drying at room temperatures (2). In the homeless patient, who is most often affected, admission may be necessary. Nonsteroidal anti-inflammatory agents are useful for pain relief, but parenteral opioid analgesics may be required. Although recovery is usually complete, severe complications, such as nerve and muscle injury and gangrene, occur infrequently. If the distinction between immersion foot and frostbite is unclear, the patient should be treated for frostbite.

Frostbite therapy is aimed at abating the specific pathophysiologic mechanisms causing tissue destruction. Rapid rewarming of tissues in a warm water bath decreases direct tissue damage caused by ice-crystal formation and greatly improves frostbitten tissue survival (10). Rapid rewarming is achieved by immersing the frozen extremity in a warm water bath at 40° to 42°C (104° to 107.6°F) for 15 to 30 minutes. Gentle motion of the extremity may aid in thawing; however, rubbing or massaging should be avoided, as this may increase tissue damage.

Temperatures <40°C delay the speed of tissue thawing, whereas temperatures >42°C can cause a superimposed thermal injury and

worsen outcome (11). Maintaining the proper temperature is best achieved with hydrotherapy whirlpools. Because most EDs do not have these devices, a warm water bath can be quickly obtained using a mixture of hot and cold tap water from a standard hospital sink. A thermometer should be used to verify the proper temperature. The water will cool quickly, and the intermittent addition of warm water or complete replacement of the bath will be necessary to maintain the desired temperature. Facial frostbite should be treated with warm water–soaked gauze or washcloths.

The extremity should be rewarmed until tissue becomes pliable and erythematous, usually occurring in 15 to 30 minutes. Rapid rewarming can be extremely painful as sensation returns, and parenteral opioid analgesia is usually required. Rapid return of skin warmth, sensation, and early formation of large clear blebs are good prognostic signs, whereas persistence of cold, anesthetic, cyanotic skin, and formation of small dark blebs portend a worse outcome. Compartment syndrome is a rare cause of persistent cyanosis, so compartment pressures should be checked in suspect cases, and fasciotomy or escharotomy may be indicated. Post-rewarming edema, which occurs within 3 hours of rewarming and persists for up to 5 days, should be treated with limb elevation. Vesicles and bullae appear 6 to 24 hours after rewarming and coincide with a renewed loss of sensation in the extremity. This secondary loss of sensation may persist until complete healing of the tissue (up to 4 years), but may be permanent (7).

Other adjunctive treatments for frostbite aim at preventing secondary tissue loss caused by inflammation and thrombosis. McCauley et al. (12) designed a protocol that has been shown to decrease the progressive microvascular ischemia that occurs in the post-thaw period (Table 359.2).

TABLE 359.2
Treatment Protocol for Frostbite

- Address systemic hypothermia and/or concomitant trauma
- Rapidly rewarm the frostbitten tissue in warm water at 40°–42°C (104°–107.6°F) for 15–30 min or until thawing is complete
- After rewarming, treat the affected tissue
  - Provide appropriate analgesia in the form of an opioid
  - Debride clear blisters
  - Leave hemorrhagic blisters intact
  - Apply aloe vera (Dermaide aloe) every 6 hrs to affected parts
  - Elevate the affected tissue/extremity and splint as needed
  - Administer tetanus prophylaxis (toxoid or Ig) as any other wound
  - Administer a nonsteroidal anti-inflammatory agent (ibuprofen 400 mg orally every 12 hrs)
  - Administer benzyl penicillin 600 mg every 6 hrs for 48–72 hrs
- For documentation, obtain photographic records of wounds, if possible
- Admit frostbite patient to a specialist unit, if possible
  - Perform daily hydrotherapy for 30–45 min at 40°C
  - Prohibit smoking

Adapted from McCauley RL, Hing DN, Robson MC, et al. Frostbite injuries: A rational approach based on the pathophysiology. *J Trauma*. 1983:23;143–147.

After rapid rewarming, most authors support the debridement of clear blisters to prevent further contact of prostaglandin- and thromboxane-containing fluid with the underlying tissues. Hemorrhagic blisters, which indicate deeper damage to subdermal plexus, should be left intact (12,13). Some authors advocate debridement of hemorrhagic blisters, but this practice can lead to tissue desiccation and, therefore, is not generally endorsed (8).

Adjunctive measures prevent progressive microvascular ischemia. Topical inhibition of thromboxane and prostaglandin is achieved with aloe vera cream (12,13). Aloe vera (Dermaide) should be applied to debrided clear blisters and intact hemorrhagic blisters every 6 hours. Oral ibuprofen at a dose of 400 mg every 12 hours (12 mg/kg/d) is used to inhibit the arachidonic acid cascade (8,13). Sterile dressings should be applied, and the extremity should be elevated to minimize subsequent edema. Edema formation increases progressive dermal ischemia and inhibits the skin's bactericidal properties, ultimately predisposing to infection (7). Although there has been no randomized clinical trial showing definite benefit, most

protocols advocate the use of prophylactic penicillin, 500,000 units IV, every 6 hours for 48 to 72 hours or until edema resolves (12). Others advocate IM or PO antibiotics for the same duration (8,13). One study demonstrated increased efficacy of topical bacitracin and silver sulfadiazine over systemic antibiotics for infection prophylaxis, although no prospective trials have addressed this topic (6). Finally, frostbite is a tetanus-prone wound, and tetanus prophylaxis should be instituted (14).

Many other adjuvant therapies have been studied to prevent progressive microvascular ischemia that occurs in the post-thaw phase of frostbite. These agents include low–molecular-weight dextran, heparin, thrombolytics, vasodilators, sympathectomy, hyperbaric oxygen, limaprost (a prostaglandin E1 analog), prostacyclin, and pentoxifylline. No studies, however, present conclusive evidence supporting their routine use (15–22). Two studies evaluating tissue plasminogen activator (tPA) in the treatment of severe frostbite have shown significantly decreased amputation rates (23,24). In general, thrombolytic therapy should only be considered within 24 hours of thawing, for deep frostbite injury with potentially significant morbidity (25) but the small number of patients precludes against a specific recommendation (23,24).

The natural history of the frostbitten extremity is described by the phrase “frostbite in January, amputate in July.” This adage describes the delay in demarcation between viable and nonviable tissues. Usually about 9 to 15 days after initial injury, severely frostbitten skin develops a black, hard, dry eschar. A line of demarcation between viable and nonviable tissue usually occurs at 22 to 45 days after injury. There have been multiple attempts to define the zone of demarcation earlier so that tissue in the transition zone may possibly be salvaged through early surgical intervention. Technetium bone scanning has been used with some success (26). However, a case report suggests that magnetic resonance angiography is superior to bone scan for the early determination of viable tissues (27). Residual pain and cold intolerance are the most common late sequelae of frostbite. Vasomotor instability resulting in

hyperhidrosis, pigment changes, skin atrophy, and post-healing ulcers also occur. Some patients request late amputation of cold-injured parts as a result of the severity of these symptoms. Osteoporosis and subchondral bone loss may occur and result in joint contracture. In children, epiphyseal damage may occur, even without skin loss.

CRITICAL INTERVENTIONS

- Completely undress the patient and address systemic hypothermia and trauma.
- Rapidly rewarm frozen tissue in a warm water bath of 40° to 42°C.
- Avoid re-exposure to cold.
- Administer adjuvant therapies as directed in Table 359.2.
- Admit almost all frostbite victims to the hospital.

DISPOSITION

With all cold-induced tissue injuries, care should be taken to ensure that patients will not re-enter the same environment that exposed them to injury. Patients with frostnip and chilblains may be discharged to follow up with a primary care provider. Patients with immersion foot can be discharged if an environment that allows for proper treatment can be provided. Patients with frostbite, conversely, should be admitted to the hospital in all but the most superficial cases.

Common Pitfalls

- Failure to differentiate frostbite from the more superficial but related injuries of frostnip, chilblains, and immersion foot.
- Discharging a patient into the same environment that caused the cold-induced injury without arranging proper protection from the elements.
- Failing to recognize superimposed vascular injury or compartment syndrome after rewarming of a frostbitten extremity.

- Failing to use a thermometer to accurately measure temperature of the warm water bath. Temperatures of 40° to 42°C are effective in reducing tissue injury, whereas those >42°C can be harmful.

CHAPTER 360 Heat-Related Illness

Eric W. Schmidt and Constance G. Nichols

Heat illness can be defined as the inability of normal regulatory mechanisms to cope with heat stress. Minor heat-related problems, such as muscle cramps, edema, rash, syncope, and tetany, account for significant morbidity. *Heat exhaustion* and *heatstroke* are major heat syndromes that may cause organ damage or death if left untreated. Among high school athletes, heatstroke is the third leading cause of death (1). In elderly patients, mortality is directly correlated with increased ambient temperature (2). Sunburn and other photodermal ultraviolet (UV) injuries may exacerbate all other heat syndromes or present separately.

Heat cramps are a result of muscle fatigue combined with water and salt depletion (3). *Heat syncope* is the result of vasodilatation, usually compounded by volume depletion or the use of drugs that interfere with cardiovascular reflexes. *Heat tetany* appears to be due to hyperventilation-induced respiratory alkalosis, resulting in decreased ionized serum calcium. It may be an attempt to compensate for exercise-induced lactic acidosis. *Heat rash* is caused by the plugging, dilation, and rupture of sweat glands following skin maceration resulting from sweating. The mechanism of heat edema is unknown.

When exposed to a variety of temperatures, humans maintain a relatively constant body temperature by balancing heat loss with heat gain. Any condition that increases heat gain or decreases heat loss may result in a major heat illness (Table 360.1). Heat gain may be from (1) increased endogenous heat production from basal metabolism and muscle activity or from an (2) environmental heat

load. For example, basal metabolism generates 65 to 85 kcal/hr, which may increase five- to sixfold with exertion. Underlying illness or stimulant drugs may also increase endogenous heat production. Hot environments decrease heat loss and increase the heat load. The average sunbather may absorb 150 kcal/hr. At rest and without heat dissipation, the average human temperature would increase 1.1°C/hr.

TABLE 360.1
Factors Predisposing to Heat Illness

Endogenous Factors	Exogenous Factors
Increased Heat Gain	
Infection	High ambient temperature
Drugs	Malignant hyperthermia
Stimulants	Direct sunlight
Hallucinogens	Dark clothing
Increased activity	
Exercise	
Seizures	
Drug withdrawal	
Psychosis	
Neuroleptic malignant syndrome	
Thyrotoxicosis	
Decreased Heat Loss	
Lack of acclimatization	High ambient temperature
Dehydration	High humidity
Hypokalemia	Restrictive clothing
Drugs that decrease sweating	Protective garments
Anticholinergics	
Neuroleptics	
Barbiturates	
Anti-Parkinson agents	
Diuretics	
β-Blockers	
Alcohol	
Extremes of age	
Skin disorders	
Cystic fibrosis	
Obesity	
Debilitated/chronic disease/elderly	
Impaired voluntary responses	

Heat exhaustion is the result of dehydration with inadequate fluid and electrolyte replacement. Water or salt depletion or both may be present. Without treatment, heat exhaustion progresses to heatstroke. *Heatstroke* is a result of severe dehydration with thermoregulatory failure, resulting in body temperatures $>40^{\circ}C$ (105° to $106^{\circ}F$) and a mortality rate of up to 70%.

Acclimatization is the process of physiologic adaptation to repeated heat stress that occurs over 10 to 60 days. It results in decreased heat production and increased heat loss for a given amount of work. Metabolic function improves through an increase in skeletal muscle mitochondria and glycogen stores, which enhances aerobic work capacity producing less heat. Cardiac efficiency is improved, with an increase in maximum cardiac output, a decreased peak heart rate, and increased stroke volume. Fluid and electrolyte balance is altered by aldosterone secretion, which helps to conserve sodium stores by both sweat and renal mechanisms and by increasing extracellular volume. In addition, the threshold core temperature for sweating is decreased, and the volume of sweat is increased. With further acclimatization, sweat volumes may decrease as well. However, potassium loss during acclimatization peaks at 8 to 10 days and often increases susceptibility to heat illness (4). Although acclimatization protects against heat illness, as the wet-bulb temperature approaches 30°C (86°F) even young well-acclimated persons are susceptible during vigorous or prolonged physical activity (1,5).

UV exposure varies 40- to 80-fold over the course of the year at any given location. UV intensity peaks between 10 AM and 2 PM daily. The degree and extent of UV injury is a direct function of the total energy absorbed. UV tissue injury occurs at multiple cellular levels. Initially there is an inflammatory reaction similar to other tissue insults. Individual response ranges from mild transient erythema to urticaria with exacerbation of underlying medical conditions, depending on exposure, skin type, *photoallergy,* or *photodrug reaction* (Table 360.2). The maximal response may be delayed up to 30 hours and last for several days.

TABLE 360.2
Drugs Causing Phototoxicity and Photoallergy

Drugs That Increase Direct Phototoxicity

Amiodarone
Doxycycline
Furosemide
Naproxen sodium
Phenothiazines
Sulfonamides

Drugs That Promote Photoallergy

Phenothiazines
Sulfonamides
Sunscreens

UVB frequencies (290 to 320 nm) are up to 1,600 times more injurious than UVA (320 to 400 nm), but there is a preponderance of UVA in the environment (6).

CLINICAL PRESENTATION

Heat cramps are painful spasms of heavily used muscle groups. They often occur in acclimatized persons, during or up to several hours after exertion. The victim often has been sweating heavily with insufficient or hypotonic fluid replacement for several days. Serum sodium levels are normal.

Heat edema is manifested by ankle and wrist swelling. It occurs in the first few days of heat exposure and sometimes results in pitting (7).

Heat rash (prickly heat) is most common early in acclimatization, in tropical areas, and with wearing of tight clothes. It is an intensely pruritic, red, papular, occasionally vesicular dermatitis. Complications include infection and the formation of large nonpruritic plugs, which take several weeks to desquamate. Advanced and extensive heat rash increases the risk for heat exhaustion or heatstroke as a result of loss of sweat gland function (1).

Heat syncope is a transient loss of postural tone, with or without brief loss of consciousness occurring early in exposure to a new heat stress. It is often preceded by dehydration or is associated with the

use of drugs that affect the body's normal compensatory mechanisms (4). By the time patients are examined, vital signs have usually normalized.

Heat tetany presents as carpopedal spasm and is frequently seen in conjunction with other heat syndromes or other causes of hyperventilation. In contrast to heat cramps, it does not involve the heavily used proximal muscles. Arterial blood gas (ABG) analysis may reveal a respiratory alkalosis.

Heat exhaustion usually occurs in nonacclimatized persons who have been working in the heat for several days. It can also occur at or below room temperature in those wearing protective garments (e.g., in nuclear, biologic, and chemical operations). Symptoms caused by water depletion include thirst, weakness, dizziness, anxiety, muscular incoordination, agitation, confusion, palpitations, oliguria, and elevated temperature. Those caused by salt depletion include fatigue, weakness, headache, anorexia, vomiting, diarrhea, and skeletal muscle cramps; thirst is absent. Body temperature is usually normal or subnormal in both types of heat exhaustion. The skin is cool and clammy, and tachycardia and hypotension are common. Most victims present with a combined picture of water and salt depletion. Laboratory findings may include hyponatremia, high urinary specific gravity, and mildly elevated serum creatine phosphokinase and liver enzyme levels. Without elimination of the heat stressor and immediate treatment, heat exhaustion may progress to frank heatstroke (7,8).

Classic *heatstroke* usually affects the very young or the debilitated elderly and develops over several days, mostly during heat waves (9). The gradual onset may result in severe dehydration. Exertional heatstroke usually occurs in a nonacclimatized younger person after a few hours of severe heat stress. Victims usually can still sweat. Vital sign abnormalities include hyperthermia (usually $>40^{\circ}C$), tachycardia, tachypnea, and hypotension. The presenting temperature may not predict severity or outcome because a high core temperature for a short period of time and a lower temperature for a longer period can produce the same injury. Widespread damage to almost every organ system, especially the cerebellum,

has been described. The central nervous system is one of the first systems involved and the last to recover. Family or witnesses may describe a malaise or flu-like prodrome. Mental confusion begins at a core temperature of 38°C, and brain function is severely compromised at temperatures >42°C. Coma, seizure activity, and abnormal posturing have been described. The liver is also particularly susceptible to heat injury. Serum transaminase levels may initially be in the thousands and peak up to 2 weeks later at more than 10,000. Coagulopathies and hypoglycemia are common. The kidneys are at high risk for acute tubular necrosis. Rhabdomyolysis may contribute to renal injury in victims of exertional heatstroke (7,8). ABG measurements usually reveal a respiratory alkalosis. Lactic acidosis may also be seen following heavy exertion (10). Death is usually secondary to disseminated intravascular coagulation, acute renal failure, liver failure, or adult respiratory distress syndrome (4,8,11).

DIFFERENTIAL DIAGNOSIS

The key to diagnosing any heat illness is a history of heat stress. During a heat wave, the diagnosis is easily considered. Vigorous exercise in moderate temperatures or working in a closed, hot environment may also result in significant heat stress. The clinician should remember the predisposing factors in Table 360.1. Rhabdomyolysis should be excluded in patients with heat cramps. Electrolyte abnormalities should be ruled out in victims of heat cramps and tetany. An extensive evaluation may be necessary to exclude other causes of edema and syncope. The differential diagnosis of heatstroke also includes infection, particularly meningitis, thyroid storm, salicylate, anticholinergic, sympathomimetic or stimulant drug intoxication, and the neuroleptic malignant syndrome.

ED EVALUATION

The history should include the duration, magnitude, and conditions of heat exposure, recent activity, the nature, progression, and

duration of symptoms, medications, drug use, and underlying medical problems. In young, healthy victims, a typical history and physical examination that reveals no other pathology is all that is necessary for a diagnosis of minor heat-related problems. Normal laboratory findings are helpful in supporting the diagnosis in questionable cases and in those with advanced age or coexisting medical problems.

The temperature should be checked with a rectal thermoresistor temperature probe capable of measuring high temperatures (up to 44°C), particularly if the temperature measured by electronic thermometer approaches its upper limit. Continuous cardiac and oxygen saturation monitoring should be performed for patients with abnormal vital signs. For most symptomatic patients, laboratory evaluation should include measurements of electrolytes, blood urea nitrogen, creatinine, glucose, creatine kinase (CK), and liver enzymes; and urinalysis. Patients with elevated levels of creatine kinase, abnormal electrolyte or liver enzyme levels, or higher temperatures (>40°C) should also have coagulation studies; calcium, magnesium, phosphorus, and uric acid measurements; blood gas analysis; a complete blood count (CBC); an electrocardiogram (ECG); and a chest radiograph (8).

KEY TESTING

- Use temperature thermistor capable of measuring high temperatures
- LABS: blood gas, CBC, electrolytes, BUN, creatinine, glucose, total CK, liver enzymes
- If >40°C coagulation studies, calcium, magnesium phosphorus, uric acid, chest x-ray, and ECG

ED MANAGEMENT

Heat cramps are treated with oral or intravenous (IV) fluid and salt replacement. Heat edema is self-limited and resolves if the limb is elevated and support hose are worn. Patients with heat rash should keep their skin cool and dry and avoid tight clothing.

Antihistamines may be given for pruritus, but powders should be avoided to prevent further plugging. Desquamating agents (e.g., salicylic acid) and antibiotics effective against staphylococci may be prescribed for secondary infection. Heat syncope is treated with rest, fluids, salt, and gradual return to activity. Heat tetany should resolve with the reversal of hyperventilation.

The treatment for heat exhaustion is replacement of fluid and electrolyte losses with isotonic saline. Orthostatic patients may require 4 L or more of IV fluids. In mild cases, oral fluids can substitute for or supplement IV fluid. Rare cases present with severe hyponatremia, requiring hypertonic saline infusion (4,7,8).

The cornerstone of the treatment of heatstroke is rapid cooling. Immersing or covering the patient in ice was not recommended in the past because it was thought that skin cooling would cause vasoconstriction and shivering and could increase the core temperature. However, recent studies have shown that ice water immersion is the most effective method of cooling heatstroke especially the exertional type. The main drawback is the need for sedation in the conscious patient and the difficulties in immersion in a hospital setting (12). Cooling rates similar to ice immersion can be achieved by immersion in 15°C water. Application of ice packs in the areas of large vessels, such as the groin and axillae, and infusion of large volumes of cool IV fluids are useful for field management if immersion is unavailable but insufficient for definitive cooling.

Other methods of cooling include peritoneal and thoracic lavage using iced dialysate with cooling rates of 0.5°C/min, but the combination of evaporative cooling (0.3°C/min) and iced gastric lavage (0.2°C/min) with water or saline is more practical and just as effective. Evaporation is maximized without inducing shivering by keeping the patient wet with lukewarm water or wet towels and blowing air over the towels with a fan. Helicopter-blade fanning has also been used (13). Cooling blankets may be adequate for patients with mild heatstroke. The rectal temperature should be monitored with a probe capable of measuring high temperatures (up to 44°C).

Cooling is continued only until the temperature drops to 38.5° to 39°C, to avoid overshooting to hypothermia. Rectal temperature

monitoring should be continued, as the patient may rebound hours later and have thermal instability for days. Along with cooling, these patients frequently need sedation, intubation, and large volumes of IV normal saline. A central venous pressure line and Foley catheter may be necessary to monitor fluid therapy. Acid–base, electrolyte, and coagulation abnormalities should be corrected. Alkaline diuresis may be needed if rhabdomyolysis is present.

Shivering may be treated with chlorpromazine (25 mg IV), benzodiazepines, or thiopental. Seizure activity is best treated with benzodiazepines or phenobarbital. Phenytoin is ineffective. Dantrolene sodium has not proven efficacious in canine studies, although there are anecdotal reports of success. Poor prognostic indicators are a serum glutamic–oxaloacetic transaminase (SGOT) level $>1{,}000$ after 24 hours, coma that lasts more than 8 hours, or a presenting temperature of $\leq 42.2^{\circ}C$ (7,8). Sunburn can be prevented by avoiding unnecessary sun exposure (especially between 10 AM and 3 PM); wearing protective clothing, hats, and sunglasses; using broad-spectrum sunscreens with a sun protection factor (SPF) of 15 or higher on exposed areas; and avoiding artificial tanning lights. Treatment is otherwise supportive. Anti-inflammatory drugs and topical aloe vera and steroid spray may be useful for mild cases. More severe cases may require therapy similar to that for thermal burns (see Chapter 46, Burns).

CRITICAL INTERVENTIONS

- Institute continuous rectal temperature monitoring.
- For heatstroke, administer large volumes of IV fluid and perform ice water immersion, evaporative (fan and water) cooling and/or gastric lavage with iced saline or water.
- Avoid provoking shivering, and if necessary treat with chlorpromazine, benzodiazepines, or thiopental.

DISPOSITION

Patients with minor heat-related problems may be discharged. Patients with heat exhaustion should be admitted to a floor bed if

they have abnormal vital signs or laboratory findings or remain symptomatic after fluid therapy. Patients with heatstroke should be admitted to an intensive care unit. Discharged patients should be advised to avoid the conditions that precipitated their illness. Acclimatization with frequent water breaks and rest periods during hot-weather activity should avoid future problems. Consultation with a dermatologist may be helpful in patients with photosensitivity reactions.

Common Pitfalls

- Failure to recognize heat-related illness as a result of nonenvironmental causes.
- Failure to assess carefully for mental status changes in potential heatstroke victims.
- Failure to obtain a timely and accurate rectal temperature in patients with suspected heat illness.
- Failure to warn patients to avoid reexposure until acclimatization has occurred.
- Prescription of medications that predispose to or exacerbate heat- or sun-related illness to patients at risk.

CHAPTER 361 High Altitude Illness

Nicholas C. Kanaan and Grant S. Lipman

BACKGROUND

Increasing numbers of people are visiting high altitude (elevations above 2,500 m [8,250 ft]) for work and recreation. In the western United States alone, more than 20 million visitors per year travel to these altitudes, with 25% to 40% of them suffering from some form of high altitude illness (5). These visitors often have pre-existing medical problems and medication regimens that may complicate the diagnosis of high altitude illnesses. Thus, practitioners require an understanding of the pathophysiology of symptoms to provide appropriate prevention, diagnosis, and treatment of high altitude illness.

High altitude illness is a spectrum of disease ranging from high altitude headache (HAH), to acute mountain sickness (AMS), to potentially lethal high altitude cerebral edema (HACE). High altitude pulmonary edema (HAPE) is specifically a pulmonary manifestation of altitude illness. AMS has been defined as presence of a headache in addition to one or more symptoms of gastrointestinal disturbance (anorexia, nausea, or vomiting), insomnia, dizziness, or fatigue in a person who has recently ascended to altitudes above 2,500 m (8,250 ft) (18). The spectrum of high altitude illness is directly attributed to hypobaric hypoxia, despite the fraction of inspired oxygen in air remaining constant at 21%. Barometric pressure decreases with increasing altitude, resulting in a decreased partial pressure of arterial oxygen (Pa_{O_2}). This self-limited disease can be debilitating when severe, and occurs

in up to 50% to 75% of hikers and mountaineers in the high mountains of the Unites States (11,21).

The incidence, severity, and duration of AMS are associated with the rate and altitude of ascent and modified by individual susceptibility, physical exertion, and high sleeping altitudes (9,19). Symptoms vary widely but remain consistent on repeated episodes in the same person, with 20% developing recurrent symptoms of AMS (6). AMS demonstrates no gender preference, but HAPE is more common in males (6). On ascent to high altitude, spontaneous diuresis occurs in response to complicated fluid shifts, increased cardiac output, and increased sympathetic tone (6,7). Increased cerebral blood flow and volume lead to ensuing hyperperfusion of the brain parenchyma (3,5). In most cases, symptoms abate in 2 to 3 days, but full acclimatization may take up to 7 days. Chronic mountain sickness, or Monge disease, may develop in some patients who do not acclimatize despite prolonged altitude exposure. Chronic mountain sickness is characterized by persistent hypoxia, polycythemia (hematocrit >60), and the development of congestive heart failure (9).

HAPE is a form of noncardiac pulmonary edema associated with elevated pulmonary arterial pressures resulting in pulmonary artery hypertension. Those suffering from HAPE have pulmonary arterial hypertension with alveolar endothelium and capillary leak. Uneven constriction of the vasculature (hypoxic pulmonary vasoconstriction) leads to scattered diffuse pattern of disease with symptoms usually occurring 2 to 4 days after ascent to altitude. HAPE develops in 0.5% to 6% of persons who ascend rapidly to high altitudes, has an overall mortality of 11%, and accounts for most of the fatalities that result from high altitude illness (12).

HACE affects an estimated 1% of travelers to high altitude and can be considered an end-stage presentation of severe AMS. Symptoms are a result of blood–brain barrier leak leading to increased vasogenic (extracellular) and cytotoxic (intracellular) edema, culminating in increased intracranial pressures causing the symptoms of encephalopathy and ataxia.

Hypobaric hypoxia can exacerbate pre-existing cardiac and pulmonary disease (9). Relative contraindications to high altitude travel include: advanced age, chronic kidney or cardiac diseases, unstable coronary artery disease, chronic obstructive pulmonary disease, pulmonary hypertension, sickle cell disease, and other diseases that compromise cardiopulmonary function (7,9).

PREVENTION

A staged, gradual ascent is the most effective way to achieve acclimatization. Remaining at 2,000 to 3,000 m (6,600 to 9,800 ft) several days before going higher, and increasing the sleeping altitude less than 500 m (1,640 ft) a day with a rest day every 2 to 3 days at altitudes above 3,000 m [9,840 ft] (12). Climbing high but sleeping low is also effective in reducing the results of hypobaric hypoxia exacerbated by nighttime hypoventilation (7). Drinking plenty of fluids, eliminating salt intake, and limiting overexertion may also decrease symptoms (6,9,12).

By causing a bicarbonate diuresis, resulting in a metabolic acidosis and a compensatory respiratory alkalosis (17), the carbonic anhydrase-inhibitor acetazolamide mimics the acclimated state of acid–base balance. Acetazolamide at a dose of 125 mg twice a day or 500 mg of the sustained-release formula each day, beginning 24 hours before ascent and continuing during the ascent to high altitude (4,17) can decrease symptoms in 30% to 50% of patients. Side effects include paresthesias, dysgeusias, and mild dehydration if fluid intake is insufficient (17).

Dexamethasone is a powerful glucocorticoid that limits transmigration of fluid across the blood–brain barrier, reducing cerebral edema, and AMS symptoms to a greater extent than acetazolamide (4,6). However, dexamethasone does not assist with acclimatization, and symptoms can return (the “rebound” effect) if glucocorticoids are abruptly discontinued before acclimatization is complete. It is advisable to avoid further ascent for at least 24 hours after discontinuation. For these reasons, dexamethasone is not considered a first line choice for prophylaxis of AMS, and caution is

is warranted if using on ascent. The recommended dose for AMS prevention is 2 mg every 6 hours or 4 mg every 12 hours. Higher doses (4 mg every 6 hours) should only be considered for military or search and rescue operations requiring rapid ascent to high altitudes (4).

Ibuprofen, 600 mg three times a day starting 6 hours before ascent can decrease the odds of getting AMS by about three, with a number needed to treat of four. The mechanism of action is thought to be the prevention of the inflammatory cyclooxygenase cascade of factors that are known to increase vascular permeability and vasodilation (11). The maximum altitude this was studied was at 3,810 m (12,500 ft), and caution should be used ascending to higher elevations with this drug than those studied.

CLINICAL PRESENTATION

Early symptoms of AMS are nonspecific and generally develop within 6 to 12 hours of arriving at altitude (range of 6 to 48 hours) (6). Headache, anorexia, nausea, vomiting, malaise, insomnia, lassitude, dizziness, and dyspnea on exertion comprise the most common constellation of symptoms (7–9,12,19). The headache is usually throbbing, worse in the morning and when supine, increases with exercise or Valsalva maneuver, and may be responsive to aspirin or ibuprofen (7). Sleep is generally poor and often exacerbates symptoms as a result of hypoventilatory hypoxia, so the patient often feels worse on waking (6,7). Findings on physical examination include tachypnea, tachycardia, and peripheral or periorbital edema, and patients may complain of decreased urine output. Tachypnea and tachycardia serve to maximize oxygenation and oxygen delivery to tissues. Despite having peripheral edema, the patient is often dehydrated and hypovolemic (6).

High altitude retinal hemorrhage, seen as flame hemorrhage, is usually asymptomatic and resolves without residual (6,9). Macular involvement is manifested by central scotoma (6). Laboratory studies may reveal mild leukocytosis, hemoconcentration, and elevated creatine phosphokinase (6,7).

Manifestations of HAPE include worsening dyspnea on both exertion and rest, cough, rales, hemoptysis, cyanosis, and orthopnea (12). The chest radiograph (CXR) reveals a normal-sized heart and diffuse bilateral patchy infiltrates, in contrast to the typical butterfly distribution of alveolar edema (7,12). Arterial blood gases may show hypoxia, hypocapnia, and respiratory alkalosis. Pulmonary function tests show decreased vital capacity and peak expiratory flow rates (7,12). The electrocardiogram (ECG) most often shows only sinus tachycardia, but sometimes shows evidence of right-sided heart strain (6,7). Patients with HAPE who undergo pulmonary artery catheterization have pulmonary hypertension with normal left atrial pressure and normal pulmonary artery wedge pressure (12).

Signs and symptoms of HACE include those of AMS plus ataxia, altered mental status, somnolence, and encephalopathy (6,7,9). Other findings may include cranial nerve palsy and papilledema. HACE can progress to coma and death within 24 hours of onset if untreated, and may leave neuropsychological sequelae, even if promptly recognized and treated. White matter edema, traditionally seen in the splenium of the corpus callosum may be seen on magnetic resonance imaging (MRI). HAPE and HACE can frequently present concurrently in the same patient.

DIFFERENTIAL DIAGNOSIS

It is important to understand that not all patients who have high altitude exposure are suffering from altitude illness. Patient presentations can mimic altitude illness or present as exacerbations of underlying medical problems. A patient presenting with altitude exposure can pose a diagnostic dilemma and thorough medical history should be taken and underlying illnesses must also be addressed. The differential diagnoses of AMS, HACE, and HAPE are shown in Table 361.1. Nonspecific symptoms of early AMS may mimic viral upper respiratory infection, gastroenteritis, or an alcohol hangover. Poor central nervous system (CNS) function in those patients exposed to adverse or extreme environments can also

be a result of hypothermia, hypoglycemia, hypovolemia, exhaustion, or even carbon monoxide toxicity (6,7,10). Pulmonary symptoms may be confused with acute exacerbations of chronic respiratory diseases such as asthma or chronic obstructive pulmonary disease (6,7). Other etiologies of noncardiogenic pulmonary edema should be considered (e.g., medications, neurologic disorders). Low-grade fever and leukocytes expand the differential to more serious infections, including pneumonia and meningitis. The differential diagnosis of CNS dysfunction also includes metabolic, psychiatric, toxic, and traumatic disorders (9). A thorough consideration of the differential diagnosis is key to appropriate and effective treatment.

TABLE 361.1
Differential Diagnosis of High Altitude Illness

AMS	HACE	HAPE
Carbon monoxide	Delirium	Asthma
Dehydration	Drug or Alcohol	Bronchitis
Diabetic ketoacidosis	Ingestion	Heart failure
Fatigue/overexertion	Hypothermia	MI with CHF
Hangover	Hyponatremia	Pneumonia
Hypoglycemia	Seizure	Pulmonary embolism,
Hypothermia	Stroke	COPD exacerbation
Migraine	Sepsis	
Viral syndrome	CNS infection	

AMS, acute mountain sickness; HACE, high altitude cerebral edema; HAPE, high altitude pulmonary edema; MI, myocardial infarction; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CNS, central nervous system.

ED EVALUATION

A history of recent, rapid ascent to high altitude or history of similar episodes at altitude should alert the physician to the potential diagnosis of AMS. The rapidity of ascent, altitude, activities, length of stay at altitude, the time of onset, nature and duration of symptoms, previous altitude exposure and pre-existing medical conditions should be noted.

The physical examination should focus on vital signs and evaluation of CNS, cardiac, and respiratory function. All patients should have an oxygen saturation measured, but pulse oximetry alone has proven unreliable in diagnosing AMS (15). A funduscopic examination for papilledema should be performed. Laboratory evaluation of patients with constitutional symptoms of AMS should include a complete blood count, electrolytes, blood urea nitrogen, creatinine, and glucose. Those with tachypnea, hypoxia, altered mental status, or abnormal findings on cardiopulmonary examination should have analysis, cardiac monitoring, an ECG, and a CXR. A CT scan of the head should be considered in those with an abnormal mental status or severe headache.

KEY TESTING

- Patients with symptoms of moderate/severe AMS, HACE, or HAPE: complete blood count, electrolytes, blood urea nitrogen, creatinine, and glucose.
- Patients with signs of HAPE, shortness of breath, tachycardia, or chest pain: ECG, CXR.
- Patients with symptoms of HACE or altered mental status: noncontrast head CT.

ED MANAGEMENT

The symptoms and management of high altitude illness are summarized in Table 361.2. In the field, descent is the most effective treatment for AMS. Second-line measures include oxygen, limiting further ascent until symptoms have resolved, and pharmacologic therapy. Patients with dehydration should be given oral fluids. Patients with vomiting should be given antiemetics and intravenous saline. Acetaminophen or a nonsteroidal anti-inflammatory agent can be given for headache.

TABLE 361.2
Symptoms and Management of High Altitude Illness

Prevention and Prophylaxis	
Travelers with history of mild-to-moderate AMS who are planning an ascent to high altitude	A staged, gradual ascent above 2,800 m, ascending in sleeping altitude <500 m/d; acetazolamide 125 mg bid for 24 hrs prior to rapid ascent; ibuprofen 600 mg q8h 6 hrs prior to ascent
Mild AMS	
Mild headache with nausea, dizziness, fatigue, sleep disturbance during first 12 hrs after rapid ascent to high altitude	Stop ascent and acclimatize; descend 500 m or more; or treat with acetazolamide 250 mg PO bid; treat headache and nausea symptoms with ibuprofen and antiemetics
Moderate/Severe AMS	
Moderate to severe nausea, headache, insomnia, dizziness, dyspnea on exertion after 12 hrs at high altitude	Descent of >500 m is primary treatment. If descent impossible, use a portable hyperbaric chamber and/or oxygen 1–2 L/min. Acetazolamide 250 mg PO bid, dexamethasone 4 mg PO or IM q6h until symptoms resolve
HAPE	
Dyspnea at rest, cough, copious sputum, severe weakness, rales, tachypnea, cyanosis, hemoptysis, tachycardia	Immediate descent. Oxygen 4–6 L/min. Minimize exertion, use a portable hyperbaric chamber; Sildenafil 50 mg PO q8h or Tadalafil 10 mg bid; Nifedipine SR 30 mg q12h; Salmeterol inhaled 125 µg bid
HACE	
AMS for 24 hrs, confusion, ataxia, poor judgment, vomiting, seizure, coma	Immediate descent or evacuation. Oxygen 2–4 L/min; use a portable hyperbaric chamber; dexamethasone 8 mg IV, IM, or PO initially, then 4 mg q6h; consider acetazolamide 250 mg PO bid

Acetazolamide is effective for treating AMS (4). Acetazolamide is also effective in treating Monge disease by reducing erythropoietin and hematocrit levels by improving arterial oxygenation and preventing further impairment of pulmonary gas exchange (17). Administration of 250 mg orally twice per day (pediatrics: 2.5 mg/kg every 12 hours) until symptoms of AMS resolve is recommended (17). Acetazolamide 125 mg before bed also helps

decrease symptoms of periodic breathing often experienced while sleeping at altitude.

Dexamethasone, 4 mg every 6 hours orally, intramuscularly (IM), or intravenously (IV) can be given for severe AMS. HACE is treated with an initial dose of 8 mg of dexamethasone followed by 4 mg every 6 hours orally, IM, or IV (7,13). In children, the dose should be 0.15 mg/kg.

Patients with moderate symptoms not improving with appropriate medications or severe symptoms require immediate descent to a lower altitude, but when descent is impossible, lightweight, portable hyperbaric chambers can be used to treat AMS. Portable hyperbaric chambers are inflatable zippered cylndrical bags with a window that simulates descent to a lower altitude when pressurized to 100 mm Hg by a foot-pump, and protected from over-inflation by a pop-off valve vent (usually 2 psi). The patient is placed in the bag, and ambient air is pumped in with or without supplemental oxygen (19).

HAPE should be treated initially with oxygen, and evacuation to a lower altitude while minimizing exertion (1,12). The calcium channel blocker nifedipine is effective in preventing and treating HAPE (2). Nifedipine SR 30 mg twice daily is the recommended dose both for HACE prophylaxis and treatment. Sildenafil 50 mg every 8 hours or Tadalafil 10 mg twice daily has also been shown to decrease pulmonary artery pressure, improve oxygenation, and decrease subjective symptoms in patients with HAPE (16). Sildenafil at 25 mg orally three times daily can be used chronically (up to 3 months) for the treatment of high altitude pulmonary hypertension (1). Hypotension may occur, especially in the setting of additional medications, such as nitroglycerin or α-blockers. The inhaled beta-agonist Salmeterol 125 μg bid can also be helpful as supplemental therapy in the treatment of HAPE (20).

Continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) by mask or endotracheal intubation and mechanical ventilation with positive end-expiratory pressure may be necessary for patients with respiratory failure (8). Diuretics are not helpful and may be harmful in patients with underlying

hypovolemia. On the contrary, fluid therapy may be required for the treatment of dehydration. If recognized early and treated aggressively, nearly all young, physically fit, otherwise-healthy patients with all forms of AMS will improve quickly, often with full resolution of symptoms within 24 hours.

CRITICAL INTERVENTIONS

- Administer acetazolamide and dexamethasone to patients with AMS and HACE.
- Administer oxygen and positive airway pressure ventilation by mask or endotracheal tube to patients with severe HAPE.
- Descend to lower altitude for severe AMS, HAPE, and HACE.

DISPOSITION

Young, healthy patients with mild to moderate AMS may be discharged with instructions not to resume ascent until after symptoms have subsided and only if preventative measures are taken. Medications should never be used to allow further ascent with persistent symptoms. Patients who are asymptomatic when seen in the ED after descent may be discharged with the proviso that return to altitude may result in recurrence of symptoms and appropriate acclimatization techniques should be followed. Patients with HAPE, HACE, severe AMS, moderate AMS with persistent symptoms, complications such as chest pain, ECG evidence of ischemia, or other significant ongoing medical problems should be admitted for supportive care.

Common Pitfalls

- Failure to consider the diagnosis of AMS in patients who become ill after rapid ascent to high altitude.
- Failure to consider pre-existing conditions, underlying disease, or a thorough differential diagnosis when treating patients for altitude illness.
- Treatment of AMS with medications to allow for further ascent or continued exposure.

- Failure to use adjunctive medications and hyperbaric therapy (if available) when descent is not immediately possible.
- Failure to evacuate seriously ill patients to lower elevations in a timely manner.

ACKNOWLEDGMENTS

CHAPTER 362

Diving Injuries

Brian K. Snyder

Underwater diving, with or without the breathing of compressed gas, usually takes place without incident. However, injuries during diving can occur. These injuries are generally secondary to pressure changes (barotrauma) or the effect of gas bubbles in the vascular system and tissues (arterial gas embolism [AGE] and decompression sickness [DCS]). Other injuries associated with compressed air diving include gas toxicity and immersion pulmonary edema. Aviators and others exposed to hypobaric environments can be similarly injured, also as a result of atmospheric pressure changes.

Any discussion of diving injuries requires an understanding of gas physics (Table 362.1). In diving medicine, pressure is commonly referred to in units of atmospheres absolute (ATA) or feet of seawater (fsw) (Table 362.2). As the most basic concept, pressure and volume are inversely related (Boyle law). Changes of volume and pressure in gas-containing organs of the body during descent and ascent lead to barotrauma. According to Dalton law and Henry law, compressed gas breathing at depth will lead to an increase of partial pressures of gas within the lung, vascular system, and tissues of the diver. A subsequent decrease in ambient pressure allows the gas to expand in volume and this is what can lead to DCS.

TABLE 362.1
Gas Laws

Boyle law: Given a constant temperature, the pressure and volume of an ideal gas are inversely related.

Dalton law: The total pressure exerted by a mixture of gases is the sum of the partial pressures of each gas.

Henry law: At equilibrium, the quantity of a gas in solution in a liquid is proportional to the partial pressure of the gas.

TABLE 362.2
Pressure Units and Equivalents

1 ATM = 760 mm Hg = 14.7 psi = 101.325 kPa = 33 fsw

At a depth of 66 fsw, total pressure would be 3 ATA (atmospheres absolute): 2 ATM for the pressure exerted by the water column and 1 ATM for the pressure of the atmosphere at sea level.

ATM, atmosphere; fsw, feet of seawater; kPa, kilopascal (SI units); mm Hg, millimeters mercury; psi, pounds per square inch.

Barotrauma occurs either during descent (more common) or ascent (more dangerous). Structures potentially injured during descent are the middle and inner ear and the sinuses. The lung is the structure most likely to be injured during ascent, but fortunately, this is uncommon.

DCS or “the bends” occurs during ascent and is the result of the occlusive and inflammatory effects of inert gas bubbles in the tissues and vascular system (1). At depth, inert gas will diffuse into and eventually saturate the tissues. During a controlled ascent, the gas leaches out of the tissue slowly in equilibrium with the saturation and does not form physical bubbles. If the ascent is too rapid, the ambient pressure decreases too quickly for the gas to stay dissolved and gas bubbles will form in the tissue and vascular system. The exact mechanism of bubble formation is unclear, although pre-existing micronuclei of gas may serve as the nidus for further bubble growth (1). In addition, inflammatory vascular microparticles resulting from decompression stress may be the mechanism of DCS (2). Given that bubbling often occurs without symptoms, the presence of bubbles are necessary but not sufficient to cause DCS, suggesting that there is a threshold beyond which symptoms occur.

Divers use decompression tables or special diving computers to determine safe dive exposures. Although unusual, DCS can occur even when dives conform to accepted decompression tables or computer algorithms. Factors that increase the risk of DCS include multiple dives, rapid ascent, and flying following a dive. Symptoms from DCS may improve during a subsequent dive (essentially recompression therapy) but can get worse on resurfacing (as the inert gas load increases). Because flying after diving further decreases pressure and may elicit or worsen DCS symptoms, divers are advised to refrain from flying for at least 12 to 24 hours after the last dive (3).

Bubbles may form in the circulation (usually the low-pressure venous system) or directly in tissues. Venous bubbles may cross right-to-left shunts in the heart (e.g., a patent foramen ovale) or the lungs and arterialize, leading to AGE. The pathophysiology of spinal cord DCS appears to be initial bubbling in the venous plexus system, causing first a decrease and then complete cessation of venous blood flow from the cord. Decreasing venous blood flow prevents dissolved nitrogen in spinal cord tissues from off-gassing, thereby forming in situ bubbles within the spinal cord (4).

Other mechanisms beside direct ischemic effects are prominent in DCS and AGE. The air–blood and air–endothelial interfaces are highly reactive, and initiate thrombotic and inflammatory processes. This causes leaky endothelium, leading to third spacing of fluids. Furthermore, adhesion and activation of neutrophils on the endothelium leads to the release of reactive oxygen species and other tissue-toxic neutrophil-derived moieties, causing a histopathology similar to an ischemia/reperfusion injury (5). Again, microparticles may be a mediator of this inflammation (2).

Inert gas, especially nitrogen, can cause narcosis at depth. Typically, symptoms start at depths of 100 ft or greater if breathing air. Further depth increases symptoms, including loss of fine motor skills and high-order mental processes and causes behavior similar to alcohol intoxication and may make activities at depth difficult or dangerous. Unconsciousness occurs below 300 ft. Symptoms

improve on ascent. In addition, nitrogen narcosis may impair the diver's memory of events during the dive (6).

Oxygen toxicity mainly affects the pulmonary system and the central nervous system (CNS). Pulmonary oxygen toxicity is unusual but can occur at partial pressures of oxygen at or below 1 ATA, as seen in patients requiring prolonged mechanical ventilation with high fractions of inspired oxygen. Symptoms include dyspnea, chest pain, cough, and decreased pulmonary function.

The CNS effects of oxygen usually begin to occur at depths when the partial pressure of oxygen in the breathing mixture is >1.6 ATA (220 fsw if breathing compressed air). Some divers may breathe oxygen-enriched air ("Nitrox") with fractions of oxygen of 32% to 36%. Cerebral oxygen toxicity can occur at lesser depths and actually is the factor that limits diving depth with Nitrox. In addition, there are "oxygen rebreather" systems where the diver breathes in a continuous circuit of gas with more than 95% oxygen. With these systems, cerebral oxygen toxicity can occur at depths as little as 25 ft.

Clinical hyperbaric oxygen (HBO) treatments use oxygen partial pressures up to 3 ATA, although oxygen toxicity in hyperbaric chambers is unusual. Divers are more prone to cerebral oxygen toxicity as they are exerting themselves in a cold, wet environment. Cerebral oxygen toxicity is affected by cerebral blood flow and $PaCO_2$. The mechanism is under investigation but may be caused by an increase in nitric oxide production (7).

CLINICAL PRESENTATION

The most common form of barotrauma seen in diving is a middle ear "squeeze." During descent, air within the middle ear contracts as the pressure increases, causing inward movement of the tympanic membrane (TM). If the pressure in the middle ear is not equalized (by opening the eustachian tube with a Valsalva or other maneuver) the TM can be injured (8). Bleeding can occur within the TM or within the middle ear space, leading to a hemotympanum, or the TM may rupture. Similarly, a closed space in the external ear canal

from occlusive material (e.g., wax or ear plugs) can bend the TM outward during descent and cause injury. The diver with otic barotrauma will present with a history of difficulty clearing the affected ear, pain, a conductive hearing loss, and sometimes vertigo.

Without adequate sinus ventilation during descent, pressure will increase in the sinuses, leading to pain and possibly a bloody nasal discharge as the mucosa is stripped from the periosteum. This may cause dramatic bleeding into the diver's face mask.

The inner ear can also be injured secondary to pressure changes. During descent, a forceful Valsalva maneuver can damage the round or oval window of the cochlea, potentially forming a fistula. The diver with inner ear barotrauma will present with a history of difficulty clearing the ears, the use of a forceful Valsalva maneuver, and sudden onset of severe vertigo, tinnitus, and hearing loss. On examination, the patient will have severe vertigo, a sensorineural hearing loss, and possibly a positive "fistula test." The fistula test involves insufflation of air onto the TM. The test is positive if eyes deviate to the contralateral side. The patient with inner ear barotrauma may also have signs of middle ear barotrauma (8).

During ascent, gas volumes increase as the pressure decreases. Generally, divers have no problems with their ears or sinuses during ascent (with some exceptions, see alternobaric vertigo below), because gas leaves the middle ear as the eustachian tube opens spontaneously or leaves the sinuses through the ostia. Barotrauma of ascent generally involves the lung. The most common scenario leading to pulmonary barotrauma is a panicked, rapid, or out-of-air ascent. With breath-holding during ascent, the glottis is closed, and the expanding gas cannot escape, causing rupture of alveoli. Congenital or acquired gas-trapping pulmonary processes (e.g., a cyst or bleb or asthma) may also result in lung barotrauma. Once the lung ruptures, gas can collect in the mediastinum (pneumomediastinum), interstitium of the lungs (pulmonary emphysema), in the pleural space (pneumothorax), or in the vascular system as an AGE. Divers with pneumomediastinum or pneumothorax will present with chest pain, dyspnea, and possibly

subcutaneous emphysema. A chest radiograph will generally show the abnormal collection of gas but is not completely sensitive (4).

Although gas from an AGE will systemically embolize, the most prominent organ involved is the brain (cerebral arterial gas embolism or CAGE). A diver with CAGE will develop symptoms during ascent or immediately on surfacing. Symptoms include altered level of consciousness, hemiplegia or hemiparesis, seizure, or other cerebral dysfunction. Sudden death may occur. If the patient survives the initial event, he may spontaneously improve as gas is forced through the cerebral vascular system by a spike in blood pressure. Any neurologic symptoms in the setting of pulmonary barotrauma should be thought to be secondary to CAGE and appropriate therapy quickly initiated (4). CAGE can also be caused by the iatrogenic introduction of gas into the vascular system, such as the inadvertent injection of air, the insertion or removal of central vascular catheters, neurosurgical procedures or procedures requiring cardiopulmonary bypass, cesarean section, or peritoneal insufflation for laparoscopy. Symptoms and classification of DCS depend on the organs affected. Type I DCS (“pain only”) involves the joints, extremities, and skin. Lymphatic obstruction can cause lymphedema, which usually takes days to resolve despite recompression therapy. Type II DCS (or “serious” DCS) includes “neurologic DCS” involving the CNS (mainly the spinal cord in compressed-air sport divers), vestibular DCS (“staggers”), and cardiopulmonary DCS (“chokes”).

The symptoms of DCS usually occur minutes to several hours after surfacing, but cases of DCS symptoms occurring days after diving have been reported. The pain of type I DCS is typically described as deep and unrelieved, but not worsened, with movement. Since divers can injure themselves in other ways (strains, direct trauma), pain from DCS can be confused with or attributed to pain from these injuries. Distention from bubbles in ligaments, fascia, and long bones or the activation of stretch receptors caused by bubbles in tendons are thought to be the mechanism of pain. This mechanism is supported by the rapid improvement of type I DCS symptoms with recompression. The most common locations for type I DCS are knees

and shoulders, and frequently only a single joint is involved. Diffuse and difficult to describe back pain may herald the more serious signs of spinal cord DCS.

The classic description of neurologic DCS (type II) begins with this sensation of truncal constriction or girdle-like pain. A "wooly feeling" may begin in the feet and develop into an ascending paralysis. This produces a presentation similar to a transverse myelitis. This form of neurologic DCS is usually rapid in onset and has a tendency to affect the lower cervical and thoracic regions.

In type II DCS, neurologic deficits do not necessarily follow distinct spinal cord syndromes seen with trauma or ischemia. Furthermore, because lesions are scattered throughout the spinal cord, a definitive "level" is frequently not found. Incontinence and sexual dysfunction from autonomic involvement is common.

Pulmonary DCS, or "the chokes," is generally seen only after prolonged, deep diving. This syndrome is caused by large numbers of pulmonary artery bubbles and presents with cough, hemoptysis, dyspnea, substernal chest pain, or cardiovascular collapse. Vestibular DCS, or "the staggers," also usually occurs after deep, long dives, although it is increasingly being reported in sport divers. It presents with vertigo, hearing loss, tinnitus, and disequilibrium. These symptoms are similar to inner ear barotrauma; however, they occur more gradually and after ascent whereas other historical clues are also helpful in distinguishing the two distinct processes (4).

Cerebral oxygen toxicity manifests itself with twitching, nausea, paresthesias, dizziness, and seizures. A seizure may be the initial manifestation of cerebral oxygen toxicity and may cause drowning when it occurs in the water. Immersion pulmonary edema can occur while diving and swimming. Typical symptoms include dyspnea, chest discomfort, and coughing of pink frothy secretions. The mechanism of this condition is unknown. It is not caused by decompression. Hydrostatic forces, thermal stress, and possibly increased capillary permeability may be involved (9,10).

DIFFERENTIAL DIAGNOSIS

The diver with vertigo may present a diagnostic challenge. Vertigo caused by transient unequal clearing of the ears is called alternobaric vertigo and can be confused with more dangerous processes such as inner ear barotrauma or vestibular DCS (Table 362.3). The diagnosis can be complicated by a combination of injuries: for example, a diver sustains inner ear barotrauma, causing panic, leading to a rapid ascent and CAGE. The major confusion in the diagnosis of vertigo is differentiating inner ear barotrauma from CAGE. Because HBO treatment for CAGE can worsen inner ear barotrauma, this distinction is important. However, if one cannot distinguish between the two conditions or both may have occurred, myringotomies to decompress the middle year can be performed before commencing HBO.

TABLE 362.3
Differential Diagnosis of Vertigo in the Diver

Cause of Vertigo	Risk Factors	Onset of Symptoms	Symptoms and Physical Examination Findings
Alternobaric	Unequal clearing of ears	During descent or ascent	Self-limited
Middle ear barotrauma	Difficulty clearing ears	Occurs during descent	Signs of barotrauma on otoscopic examination, conductive hearing loss
Inner ear barotrauma	Difficulty clearing ears, forceful Valsalva	Occurs during descent, occurs immediately after attempt to clear ears	Severe vertigo, tinnitus, sensorineural hearing loss, possible fistula test (see text), may have signs of middle-ear barotraumas
Vestibular decompression sickness	Deep, prolonged dives, switching of breathing gas	Occurs after dive completion, usually 15 min to hours	May have other signs of DCS
Cerebral arterial gas embolism	Rapid or panic ascent	Occurs on surfacing or within minutes of surfacing	Will have other signs of CAGE (altered or loss of consciousness, hemiplegia) (see text)

Another difficult distinction is between CAGE and DCS. In fact, the two conditions can occur concurrently (type III DCS) (4). Some authorities do not distinguish between the two entities and call all bubble-related diving injuries decompression illness (DCI). The argument for this approach is that sometimes DCS and AGE cannot be reliably distinguished and the primary treatment is the same. Some oppose the term DCI because although sometimes indistinguishable, the two processes can often be separated. In addition, although primary therapy may be the same, adjunctive therapies may be specific (e.g., lidocaine in CAGE), and research may be hindered by such a lack of distinction.

CAGE usually occurs immediately or soon on surfacing after a rapid or uncontrolled ascent with mainly cerebral symptoms, such

as altered level of consciousness, seizure, or hemiplegia. On the other hand, symptoms of DCS begin minutes to hours after the dive and although cerebral symptoms can occur, neurologic symptoms and signs usually refer to the spinal cord. CNS trauma, near-drowning, and hypothermia should be considered in the differential diagnosis of these conditions.

ED EVALUATION

The history should include details regarding the dive profile, symptom latency, severity, progression, and pre-existing health. Vital signs should include measurement of oxygen saturation. The physical examination should focus on the cardiopulmonary and neurologic systems and the ears, nose, and throat. Patients with chest signs and symptoms or altered mental status should have an ECG and undergo continuous cardiac monitoring. Evaluation for cardiac ischemia or dysfunction should be considered in patients with an abnormal ECG, pulmonary edema, or unexplained chest complaints, particularly those with risk factors for cardiovascular disease. Although routine laboratory studies are not helpful in the diagnosis or treatment of diving injury, they may evaluate for other conditions, if clinically indicated.

KEY TESTING

A chest radiograph is likely the only “routine” test in evaluating injured divers with potential cardiopulmonary complaints, CAGE or DCS. CNS imaging should not delay definitive treatment (HBO).

ED MANAGEMENT

Patients with uncomplicated barotrauma to the middle ear or sinuses should be treated symptomatically with decongestants such as oxymetazoline (Afrin) or pseudoephedrine and analgesics. Antibiotics can be prescribed in the cases of a perforated TM or sinus barotrauma occurring in contaminated water.

Patients with inner ear barotrauma should constantly sit up and avoid maneuvers that increase intracranial pressure (nose blowing,

etc.). Some otolaryngologists advocate conservative treatment with antivertigo and antiemetic drugs such as meclizine (Antivert), reserving surgical intervention to those who do not improve spontaneously, although others advocate for immediate surgical exploration (8).

Patients with pneumomediastinum but no sign of CAGE can be managed conservatively. Those with more than a very small pneumothorax should have it evacuated, and a chest tube must be inserted if HBO therapy is to be employed.

Patients with suspected DCS or CAGE should receive 100% oxygen by nonrebreather face mask or endotracheal tube if necessary to ensure an intact airway. Recompression with HBO should occur as soon as possible, with transfer to a recompression center if necessary. Outcomes seem to correspond to the timeliness of HBO therapy. Although there are several recompression treatment tables employed in the treatment of DCS or CAGE, the most common is the US Navy Treatment Table 6 (with a maximum treatment pressure of 60 ft or 2.8 ATA). Lower treatment pressures have also been used with good results (11). If symptoms do not fully resolve, some centers will continue HBO treatments daily or twice daily until symptoms plateau. Divers with DCS have responded to HBO days after injury, and therefore this should be instituted even if presentation is delayed.

There are several beneficial physiologic effects of HBO. Increased pressure reduces bubble size. Increased partial pressure of oxygen dissolved in serum creates a gradient, causing nitrogen to move from bubbles into serum, increasing off-gassing of inert gas. Oxygen, in turn, moves into bubbles, but because it is metabolically active, it subsequently moves into cells, leading to further dissolution of bubbles. HBO increases the oxygen dissolved in the plasma which increases oxygen delivery to ischemic tissues, as well as decreasing edema and intracranial pressure, and reducing the adherence and activation of leukocytes on vascular endothelium (12).

Divers with CAGE should be kept supine with the head in a neutral position. The Trendelenburg position should not be employed.

Nondextrose-containing isotonic intravenous (IV) fluids should be infused to preserve tissue perfusion in divers with DCS and CAGE. Various pharmaceutical adjuncts have been used in the treatment of DCS and CAGE, including aspirin, corticosteroids, and heparin but animal studies and human experience have generally shown no definite benefit (13). IV lidocaine in the treatment of CAGE has been shown to be effective in animal models and in a human study examining neuropsychiatric outcomes after cardiopulmonary bypass (where neuropsychiatric deficits are thought to be secondary to intravascular air) (14). Typical cardiac doses are generally used.

Oxygen and nitrogen toxicity and immersion pulmonary edema resolve spontaneously. Treatment is primarily supportive. If immersion pulmonary edema is severe or persistent, standard treatments for this condition can be administered (9).

Clinicians unfamiliar with the treatment of underwater diving injuries should consult a diving or hyperbaric medicine specialist or the Divers Alert Network (DAN; phone: 1-919-684-9111; website: http://www.diversalertnetwork.org). DAN has staff available 24 hours a day to provide assistance to divers and clinicians and can provide the location of the nearest hyperbaric facility.

CRITICAL INTERVENTIONS

- Obtain a chest radiograph on patients with cardiopulmonary complaints. If the chest radiograph is normal, consider evaluation for acute coronary syndrome or other cardiac or pulmonary process, especially if the dive profile and symptoms do not suggest a high probability of DCS or AGE
- Administer oxygen and IV fluids and arrange for HBO therapy for patients with DCS and CAGE.
- Remember that medical conditions not related to barotrauma or decompression can occur in or around the water and the physician must be careful to evaluate for such processes.

DISPOSITION

Patients with pulmonary barotrauma but without evidence of CAGE do not require recompression therapy. Those with suspected DCS or CAGE should be transferred to a facility capable of providing HBO therapy. A diver may require hospitalization or repetitive treatments after initial therapy.

Given that treatment of inner ear barotrauma is controversial, emergent otolaryngology consultation may be obtained for patients with this condition.

Patients with barotitis or sinus barotrauma should not return to diving until symptoms resolve. Those with a perforated TM must not dive until it heals. Otolaryngology referral in 4 to 6 weeks is warranted.

Ideally, divers with DCS or CAGE should be examined by a physician experienced or trained in diving medicine before returning to diving. Counseling of divers experiencing immersion pulmonary edema is difficult as it cannot be predicted who will experience another episode.

Common Pitfalls

- Failure to appreciate that significant barotrauma can occur at shallow depths.
- Failure to consider the possibility of DCS or CAGE in any patient with neurologic symptoms after underwater diving.
- Failure to consult a diving or hyperbaric medicine specialist or the Divers Alert Network for advice and to consider HBO even when the diagnosis is not clear.
- Failure to consider inner ear DCS or barotrauma in the vertiginous diver and failure to differentiate between the two processes.
- Failure to have divers' follow-up with a physician experienced in diving medicine beforereturning to diving.

CHAPTER 363

Drowning (Submersion Injuries)

Eric W. Ling

The World Health Organization defines drowning as “the process of experiencing respiratory impairment from submersion/immersion in a liquid medium.” This is further subdivided into drowning with subsequent fatality, morbidity, or no morbidity; a clinical submersion event without respiratory impairment is simply a water rescue. Drownings occur most frequently in a bimodal distribution with one peak in the toddler years, generally associated with lapses in supervision, and another peak in the late adolescent and early adult years associated with swimming, water sports, and substance intoxication (1). Respiratory dysfunction and ensuing anoxic brain injury are the primary drivers of morbidity, though hypoxic injury to the heart, liver, and kidneys also plays a role. Concurrent trauma or comorbid medical conditions must always be considered, including events that may precipitate drowning such as intoxication, seizure, or primary cardiac arrest. Hypothermia and environmental exposure often complicate resuscitation (see Chapter 358).

The pathophysiology of drowning begins with submersion in a liquid and an inability to reach safety or maintain the mouth and nose consistently above the surface. Voluntary breath holding follows, lasting up to a minute, then involuntary aspiration as the respiratory drive overwhelms resistance. This initial aspiration often generates laryngospasm that prevents further aspiration, and the patient can swallow copious amounts of liquid working to inhale against a closed glottis. Laryngospasm relaxes as the brain becomes

hypoxic. Significant aspiration then occurs until the respiratory drive is blunted by brain anoxia and apnea results. The initial sympathetic surge generates tachycardia, but progressive hypoxia leads to bradycardia, pulseless electrical activity, and finally asphyxial asystolic arrest (2).

Aspiration washes out surfactant and disrupts the alveolar membranes, decreasing lung compliance with a corresponding five- to ninefold increase in the work of breathing. Greater membrane permeability permits the development of massive pulmonary edema —a given aspiration may generate three times that quantity in pulmonary edema (3). Bronchospasm also arises from direct irritation of airway epithelium. Theoretical differences between fresh and salt water aspirations are born out in microscopic analyses of injured lung tissue when greater than 11 mL/kg is aspirated, but appear to have minimal clinical effect in nonfatal human drownings where aspirations typically involve less than 3 to 4 mL/kg (2,3).

The brain is exquisitely sensitive to the partial pressure of oxygen. In healthy volunteers, PaO_2 drops to 43 mm Hg within 85 seconds of breath holding and strenuous activity (3). This progressive hypoxia prior to arrest differentiates asphyxial arrest from primary cardiac arrest and results in far greater anoxic brain injury for circulatory arrests of comparable duration. Reperfusion injury is believed to be considerable, and cerebral edema develops in proportion to the degree of brain injury (4). Subtle cognitive deficits may persist despite a normal neurologic examination, and for toddler drownings, the full extent of injury may not be evident until the child begins schooling (5).

Hypoxia causes cardiac, liver, and renal dysfunctions. Cardiac injury is more likely with pre-existing coronary artery disease or heart disease. Liver injury is generally mild while renal injury may rarely require dialysis but remains reversible. Renal injury from hemoglobinuria or myoglobinuria has been reported but is likely related to concomitant circumstances and not to the pathophysiology of drowning.

Up to 10% of drowning victims have minimal fluid aspiration on autopsy. While this was traditionally thought to be from laryngospasm preventing aspiration ("dry drowning"), there is no supporting literature and it is more likely that, in these cases, apnea secondary to another etiology preceded the submersion event (3). The "immersion syndrome" describes sudden cardiac arrest upon immersion to cold water, mediated by a sympathetic surge from cold water immersion and subsequent dysrhythmias (6). Prolonged QT syndromes are vulnerable to immersion syndrome, though autopsy studies have not found evidence of associated genetic mutations in unexplained fatal drownings (2).

Hypothermia is common due to submersion in cold water and ongoing cooling during rescue and resuscitation. Hypothermia dramatically reduces brain metabolism and offers neuroprotective effects with reasonable neurologic recovery after 66 minutes of submersion in ice water (5). In general, hypothermia portends a poorer prognosis than normothermia, presumably due to increased duration of submersion, prolonged transport, or insufficient circulation. Hypothermia is responsible for many of the arrhythmias noted in drowning victims, most typically atrial fibrillation. In severe hypothermia, ventricular arrhythmias may be present but are rare with a core temperature $>32^{\circ}C$ and, if present, should raise the prospect of additional occult pathology.

CLINICAL PRESENTATION

Drowning victims may be awake, lethargic, combative, comatose, or in cardiac arrest on presentation. A history of coughing, choking, or vomiting is common. Though the history may clearly identify a submersion event, drowning injury should also be considered in any patient with altered mental status found near a body of water. In mild cases, the pulse, blood pressure, and respiratory rate are often elevated, but with severe hypoxia vital signs may be decreased or absent. Varying degrees of hypothermia are often present. Aspirated or regurgitated food, water, or other foreign material may be present in the mouth and airway. Rhonchi, rales, or wheezing can

be audible on pulmonary examination. Gastric distention is common. Associated traumatic injuries may also be present. Victims of scuba diving accidents may have signs and symptoms of concomitant barotrauma and decompression sickness (see Chapter 362). In severe cases, decorticate or decerebrate posturing, flaccid paralysis, unreactive pupils, or absent corneal, brainstem, and deep tendon reflexes may be present. With the exception of clear signs of death, such as decapitation, hemisection, or putrefaction, moribund presentations do not exclude aggressive resuscitation. Between 10% and 20% of patients presenting with coma and initially fixed and dilated pupils will recover completely.

DIFFERENTIAL DIAGNOSIS

In patients found unresponsive in or near a body of water or other fluid, the possibility of preceding trauma (especially to the head and neck), alcohol or substance intoxication, myocardial infarction, seizure, cerebrovascular accident, attempted suicide or murder, child abuse or neglect, cerebral air embolus (in scuba divers), and other causes of altered mental status should be considered.

ED EVALUATION

The history should include details such as estimated submersion time, medium, and temperature; events surrounding the submersion; level of consciousness and vital signs at the scene; and signs, symptoms, and treatment before arrival. For children who fall into pails of liquid (e.g., detergent, insecticide) or industrial workers who may be submerged in a medium other than water, the type of liquid and its potential toxicity should be established. A submersion near rocks, near high ledges, in heavy surf, while engaging in motor sports, or while diving, raises suspicion for concomitant traumatic injury.

If the patient arrives in critical condition, evaluation begins with evaluation of airway patency, spontaneous respirations, and palpation of a pulse. Of note, in hypothermic patients, pulses may be extremely difficult to palpate and assessment of circulatory

function requires a full minute palpating central pulses (8). If available, bedside cardiac ultrasound enables more rapid appraisal of cardiac function.

After an initial assessment, physical examination focuses on vital signs, cardiopulmonary status, and neurologic findings. Continuous monitoring of arterial oxygen saturation and cardiac telemetry is essential. Temperature should be taken using a low-reading thermometer: rectal if awake or esophageal if intubated. Serial coma grading (for instance, the Glasgow Coma Scale) is helpful in monitoring progress. In all symptomatic and comatose patients, a chest radiograph should be obtained. The development of pulmonary edema is often delayed, and repeat chest radiographs are recommended whenever symptoms worsen or shortly before ED discharge, even if a patient is asymptomatic (2,9). Electrocardiogram (ECG) is warranted in most symptomatic patients.

Baseline laboratory studies should include a point-of-care blood glucose, an arterial or venous blood gas analysis, lactate, complete blood count, electrolytes, glucose, blood urea nitrogen, creatinine, and urinalysis. Critically ill patients should have cardiac enzyme; liver function tests; calcium, magnesium, and creatine kinase measurements. Urine drug testing may suggest a cause for the drowning.

In persistently altered patients or patients with a history of trauma, a computed tomography (CT) scan of the head should be performed. Routine cervical spine imaging is not indicated, as demonstrated by a series of 2,244 drowning victims which found a 0.49% prevalence of cervical spine injuries, with injuries only in those with a history of trauma or traumatic examination signs (7). Magnetic resonance imaging (MRI) is more sensitive for cerebral edema and anoxic brain injury than CT but neither study is sufficient to inform prognosis in the ED. Since cerebral edema develops over time, MRI becomes significantly more helpful in guiding therapy and prognosis discussions when obtained 3 to 4 days after the drowning event (4).

KEY TESTING

- Core temperature with a low-reading temperature probe
- Chest radiograph initially and, if discharging from the ED, prior to discharge
- Initial laboratory studies: blood gas, lactate, glucose, complete blood count, electrolytes, blood urea nitrogen, creatinine, urinalysis
- Secondary laboratory studies if pertinent: cardiac enzymes, liver function tests, calcium, magnesium, creatine kinase, urine drug screening
- Advanced imaging: CT head for persistently altered or traumatic patients; cervical spine imaging only with a history of trauma or traumatic examination signs

ED MANAGEMENT

Rapid prehospital response and early initiation of resuscitation are the principal factors influencing morbidity and mortality. Rescuers must be cognizant of personal danger during rescue attempts, as dangerous conditions may result in injury to rescue teams. In contrast to basic life-support recommendations to initiate resuscitation with chest compressions, the resuscitation of drowning victims should start with rescue breathing, while still in the water if possible (8,10). Chest compressions are ineffective in the water and must await extrication to a dry firm surface. The Heimlich maneuver is indicated only when there is clear foreign body obstruction of the airway. In other cases, the Heimlich maneuver and postural draining techniques have no proven benefit and increase the risk of aspiration from vomiting (2,3,8,10).

Cervical spine immobilization during rescue and resuscitation is not indicated in routine drownings without history or signs of trauma (7). As noted above, cervical spine injury is rare, and immobilization attempts may significantly delay extrication while interfering with essential airway management-–optimal early airway management with rescue breathing is life saving and takes precedence over all other prehospital interventions.

After extrication, cardiopulmonary resuscitation and advanced cardiac and trauma life-support measures are instituted as necessary and by established guidelines. Immediate ED therapy is directed toward securing the airway, ensuring adequate oxygenation, performing chest compressions if necessary, reversing hypothermia, and correcting hypoglycemia and hypotension. There are no clinical, laboratory, or imaging criteria that can determine survivability on ED arrival (2–4,8,10). Thus, every arrested drowning patient should receive 20 to 30 minutes of high-quality advanced cardiac life support before discontinuing resuscitation. Hypothermic arrested patients should be rewarmed as rapidly as possible and cardiopulmonary resuscitation should continue until the patient is $>32^{\circ}C$ for 20 to 30 minutes. Traumatic injuries should be managed as usual but with emphasis on respiratory management and neuroprotective strategies.

Awake patients should be placed in a lateral decubitus position as tolerated to prevent aspiration from vomiting. After drowning with subsequent rescue breathing, the chance of vomiting is about 65%. After chest compressions, the chance of vomiting rises to 86% (8). Patients who are protecting the airway but are unable to maintain oxygen saturations above 90% on high-flow oxygen or who are becoming increasingly fatigued may benefit from a trial of noninvasive positive pressure ventilation (CPAP or BiPAP). With any type of respiratory support, hyperoxia should be avoided to reduce the brain injury associated with oxidative reperfusion stress, and the goal for oxygen saturations should be 94% to 98% (4). Bronchospasm may be present and should be treated with inhaled bronchodilators.

Patients who are inadequately protecting the airway require a secure endotracheal intubation; due to the high airway pressures required to inflate drowned lungs with greatly reduced compliance, supraglottic airways may be ineffective (3). Ventilator settings should be set in accordance with acute respiratory distress syndrome guidelines, with high positive end-expiratory pressures (PEEPs) to recruit respiratory units and reduce ventilation–perfusion mismatch, low tidal volumes, and increased respiratory rates. Gastric

decompression by nasogastric or orogastric tube is recommended for all intubated patients. For patients with severe lung injury who cannot be oxygenated despite optimal endotracheal ventilation, consider emergent bronchoscopy to remove possible foreign bodies such as sand, mud, algae, or vomitus. With continued treatment failure, extracorporeal membrane oxygenation (ECMO) has been employed in case reports with good success (2). Corticosteroids for drowning-related lung injury have not been shown to be effective and are not recommended.

Initially clear chest radiographs may be falsely reassuring as the development of pulmonary edema can be delayed. Pediatric literature suggests that patients who are asymptomatic after 6 to 8 hours of observation are unlikely to require treatment, and this has become the standard for ED observation (2,11). Infiltrates present on chest radiograph are difficult to differentiate between pulmonary edema, chemical pneumonitis, and aspiration pneumonia. While patients with exposure to contaminated fluids (sewage, etc.) should receive prophylactic antibiotics, it is unclear which other patients benefit from antibiotic therapy. Several retrospective chart reviews show no benefit to prophylactic antibiotics and one review noted a trend toward increased resistance in pneumonia that developed on prophylactic antibiotics, but there are no prospective or randomized trials (9,12,13). The typical diagnostic clues to pneumonia are obscured in drowning: Pulmonary edema or chemical pneumonitis may mimic infectious infiltrate on chest radiograph, fever may not be clinically apparent with therapeutic hypothermia treatment, and leukocytosis is common in drowning regardless of infection. Waiting for the presence of purulent sputum or positive sputum cultures may secure the diagnosis, but pneumonia in acute respiratory distress syndrome may present as a fulminant process and delays may be lethal. Broad spectrum antibiotics, covering typical gastric aspiration as well as the *Aeromonas spp.* and *Pseudomonas aeruginosa* common in bodies of water (13), should therefore be started with a very low threshold on all critically ill patients with infiltrate on chest radiograph and one of the following: persistent tachycardia,

hypotension, or leukocytosis; fever; or failure to respond to maximal therapy.

Acidosis results from both metabolic lactic acidosis and hypercarbia secondary to inadequate ventilation. Serum bicarbonate is frequently low but does not require specific therapy as it typically resolves with appropriate oxygenation, ventilation, and circulatory support.

Hypotension may develop from primary or hypoxic cardiac dysfunction, cold diuresis, acidosis, or as a systemic inflammatory response to aspirated material. Normal saline is isotonic and is the preferred resuscitation fluid for nontraumatic drownings. Volume overload may worsen pulmonary or cerebral edema and should be avoided. Vasopressors may be employed for refractory hypotension (14).

To manage hypothermia wet clothing should be removed immediately and warm blankets applied with additional external forced air blankets or plumbed blankets for hypothermic patients above 32˚C. Patients below 32˚C or with unstable vital signs benefit from concurrent external and internal warming techniques including endovascular catheterization, thoracic lavage, and ECMO (see Chapter 358).

Data from primary cardiac arrest and newborn asphyxia suggest that therapeutic hypothermia may also be neuroprotective in arrested drowning victims (4). Hypothermic patients in arrest should not be actively rewarmed above 32˚C and any arrested drowning patient may benefit from therapeutic hypothermia with goal temperatures of 32 to 34˚C for 12 to 72 hours and slow 0.5˚C per hour rewarming. Hyperthermia should absolutely be avoided in all drowning patients (15).

In addition to appropriate oxygenation and therapeutic hypothermia, neuroprotective critical care for anoxic brain injury and cerebral edema also includes meticulous attention to seizure activity, hypocarbia or hypercarbia, hypotension, hypoosmotic state, hypoglycemia or hyperglycemia, and head positioning (4). Seizures should be treated swiftly with benzodiazepines and with antiepileptics. Electroencephalogram (EEG) should be considered for

any suspicion of nonconvulsive seizure. Because hypercarbia and prolonged hypocarbia both result in reduced cerebral perfusion, the goal is normocarbia and a $PaCO_2$ of 40 mm Hg. Arterial hypotension underperfuses cerebral tissues and a goal of normal blood pressure is essential. Hypoosmolar states, due to hypoosmolar fluids or renal wasting, increase intracranial pressure by means of an osmotic gradient, and these should be avoided. Both hyperglycemia and hypoglycemia have demonstrated deleterious effects on injured brain and normoglycemia should be maintained. Finally, appropriate position with the head midline and the head of the bed elevated to 30 degrees helps mitigate intracranial pressure. Prolonged hyperventilation, barbiturate coma, aggressive diuresis, and routine pharmacologic paralysis have no benefit in drowning. Elevated intracranial pressure likely represents the degree of cerebral edema due to anoxic injury and in and of itself may not be a driver of cerebral dysfunction. Attempts to manage intracranial pressure independently appear to have no significant impact on patient outcome and should be avoided (4).

CRITICAL INTERVENTIONS

- Resuscitate aggressively with emphasis on optimal airway management.
- Administer oxygen or noninvasive positive pressure ventilation and perform endotracheal intubation with elevated PEEP as necessary to maintain oxygen saturations from 94% to 98%: avoid hypoxia or hyperoxia.
- Assess for concomitant traumatic injury.
- Use a low threshold for initiating broad spectrum antibiotics for aspiration pneumonia in critically ill drowning patients.
- Maintain normoglycemia, normotension, normovolemia, normocarbia, normoosmolar state, and elevate head of bed to 30 degrees.
- For critical patients, induce therapeutic hypothermia to, and do not rewarm above, 32° to 34°C.

DISPOSITION

Patients who have been apneic or unconscious; those with extremes of age; those with hypoxia, dysrhythmias, ECG evidence of ischemia, or an abnormal chest radiograph; and those whose symptoms persist after ED treatment should be admitted to an appropriate level of care. Due to the delayed onset of pulmonary edema, patients are candidates for ED discharge only if they are asymptomatic after 6 to 8 hours of observation with a normal physical examination, normal oxygen saturation, and a normal chest radiograph obtained 6 to 8 hours after the drowning event. Discharged patients are instructed to return immediately if any respiratory symptoms develop (cough, sneezing, dyspnea, fever). Patients who did not have respiratory distress at any time are, by definition, considered water rescues rather than drownings. Water rescue patients who are asymptomatic on arrival with normal vital signs and physical examination may be discharged from the ED without prolonged observation. Indications for transfer include lack of necessary intensive care facilities, pulmonary specialist capable of performing bronchoscopy, or perfusionist capable of initiating ECMO.

Common Pitfalls

- Failure to appreciate that an initially moribund presentation does not preclude good neurologic recovery and, conversely, that those who present with mild symptoms may later deteriorate rapidly.
- Failure to consider the possibility of accidental or nonaccidental trauma, myocardial infarction, cerebrovascular accident, seizure, cerebral air embolism, alcohol or substance intoxication, hypothermia, and medical or psychiatric illness as precipitating or complicating aspects of drownings.
- Continuing cervical spine immobilization when it is interfering with rescue and airway management in patients with no history or signs of trauma.

- Failure to observe ED patients with a history of drowning for at least 6 to 8 hours and failure to obtain a chest radiograph shortly before discharge.
- Failure to employ neuroprotective strategies to minimize anoxic and reperfusion brain injury, including avoiding hyperoxia.

CHAPTER 364 Electrical Injuries

Scott E. Rudkin and Jennifer A. Oman

Electrocution is an infrequent cause of injury but can damage multiple organ systems. Unlike a thermal burn, electrical injuries can cause extensive internal injury without any significant sign of external injury. In the United States, electrical injuries annually kill nearly 1,000 patients, with high-voltage injuries accounting for two-thirds of the total (1). Most adult injuries occur in the workplace; electrical injuries are the fourth leading cause of traumatic, work-related deaths (2). Most fatalities from electrical injuries occur from ventricular fibrillation (VF), asystole, or interruption of the central respiratory control (1).

Luckily, the majority of household injuries have been mitigated by changes in building codes that require a ground plug. However, misuse or malfunction of home appliances still account for 200 deaths annually (3). Children constitute 30% of all electrical injuries. The large majority (60% to 70%) results from inquisitive toddlers who are exposed to electrical cords (3). The extent of an electrical injury is related to voltage, tissue resistance, type of current, duration of exposure, and electrical current pathway. For instance, although a direct lightning strike is an extremely high voltage, the short duration explains why survival is possible (see Chapter 365).

Electricity is the flow of electrons through a conductor. The flow of these electrons, the current (I), is measured in amperes and is responsible for tissue damage. The relative force of this electron flow is the voltage (V); impedance to the flow of electrons is called resistance (R) and is measured in ohms (1). All of these variables are

interrelated by Ohm's law, which defines a given current as the voltage divided by the resistance: $I = V/R$, or $V = IR$. By definition, a high-voltage injury is more than 1,000 V.

The relative resistance of various body tissues explains the relative sensitivities of certain organ systems to electrical injury. Dry, calloused skin has a resistance (40,000 to 100,000 ohms) and is relatively impervious to electrical injury, although wet, thin skin can have a resistance of $<1{,}000$ ohms and is highly susceptible (1). The least resistance is found in nerves, blood, and mucous membranes, while bones, fat, and tendons have higher resistance (2). The low resistance of nervous tissue explains why the nervous system is frequently injured in electrical injuries. Higher current densities, which are inversely related to the cross-sectional area of the current path, create more heat and more subsequent damage. Appendages, which have a smaller cross-sectional area, sustain much higher damage with a similar current than the trunk or torso. Heat generation is proportional to the current involved, the resistance of the tissue, and the duration of contact (1).

The type of current also determines injury severity. In alternating current (AC), the current flows through the conductor in a back-and-forth fashion. In the United States, the majority of residential electricity is transmitted with AC at 60 Hz (cycles/sec). AC is three times as dangerous as direct current (DC) (3). AC causes tetanic muscle contraction with a prolonged duration of contact. Flexor muscles typically are stronger than the extensors, so that muscle contraction can create a "locked-on" phenomenon where victims cannot release themselves from an electrical source. In addition, AC is more likely to induce VF (1). DC moves "directly" along a given circuit in a single direction and is safer than AC.

Lightning is a special form of DC; the voltage of a lightning bolt is extremely high ($>1{,}000{,}000$ V) but the duration of contact is very small (1 to 2 ms) (1). Lightning causes injury in four ways: direct strike (pathway through the victim), side-flash (lightning first strikes an object, then secondary discharge strikes patient), stride potential (current passes from ground, up one leg and down the other), and flash-over phenomenon (where the current travels outside the body

and causes vaporization of surface water) (3). See Chapter 365 for more details about lightning injuries.

Current pathway also determines the severity of injury. A current that traverses the body in the vertical axis is much more deadly than a similar horizontal current because virtually every organ is affected. However, a horizontal pathway from hand to hand can affect the heart or lungs and induce a dysrhythmia or paralysis of the respiratory muscles (3).

Of particular interest for emergency physicians is the utilization of electrical energy by police officers and more recently, by civilians for self-defense. These conductive electrical devices, sometimes called "stun guns" and commonly referred to as Taser devices, deliver a less-than-lethal force to subdue violent suspects. These devices deploy two to four metal barbs attached to a wire with an effective range of up to 35 ft. Upon contact, it delivers a 1,200- to 5,000-V, low-amperage (2.1-mA) pulse train, causing involuntary muscle clonus, which effectively paralyzes the assailant. The energy delivered is small and ranges between 0.07 to 0.50 J. The morbidity and mortality of these devices is low compared to those with conventional weapons (4). The danger is generally limited to secondary injuries such as sprains and contusions from falls. The overwhelming majority of deaths following the use of conductive energy devices have been from drug intoxication, underlying health defects, and acidotic delirium states. As of 2011, the manufacturer of Taser devices reports more than 3.1 million human exposures, which includes a combination of training and field use (5).

CLINICAL PRESENTATION

Electrical injuries range from a simple tingling sensation to multisystem organ failure. Frequently, the cutaneous signs of injury are limited, leading the clinician to underestimate the extent of the electrical injury. Electrical burns are best viewed as crush injuries and not thermal burns because of the potential for multisystem injury. Given their lower inherent intrinsic resistance, the cardiac and neurologic systems are most commonly injured. Electrical injury

deaths are usually due to VF (low voltage), asystole (high voltage), or respiratory arrest from central respiratory center interruption.

The heart is sensitive to electrical injury with one-third of electrical injuries having a cardiac complication (6). Injury to the myocardium occurs either from direct disruption of normal electrical signal or direct myocardial damage; the latter is more common with high-voltage injuries. Rhythm disturbances can occur with relatively low currents; 50 to 100 mA (one-half of normal household current) can induce VF in transthoracic injuries (1). In addition to VF and asystole, common electrically induced dysrhythmias include sinus tachycardia, nonspecific ST–T wave changes, ventricular tachycardia, ectopic beats, and bundle branch blocks (6). Electrical injuries can cause direct myocardial necrosis through thermal damage. Although ST–T wave changes and increased elevation of the CK–MB fraction are common, these usually are not from myocardial infarction but the elevation of the CK–MB is usually related to skeletal muscle damage (6). Patients with upper and lower body locations for entry and exit wounds are more likely to have myocardial damage (6). Electrically injured, autopsied heart specimens show scattered areas of myocardial damage with subpericardial microhemorrhage (6). Transmural necrosis is rare and usually related to injury of coronary vessels (7).

The nervous system is also highly sensitive to electrical injury; 70% of electrical injuries have some neurologic component (7). Peripheral nervous system involvement is usually peripheral neuropathy and motor dysfunction related to direct electrothermal injury, ischemia from microvascular injury, or compartment syndrome. Central nervous system (CNS) involvement can present with amnesia, loss of consciousness, confusion, impaired recall, mood lability, anxiety, depression, motor deficits, coma, or injury to the respiratory control center with resulting respiratory arrest (2,8). In addition, visual disturbances, seizures, deafness, and hemi- or quadriplegia may occur (2). In high-voltage injuries, acute insults to the spinal cord can occur from direct electrical injury or associated fractures or ligamentous injuries. C4 to C8 level injury is most common with hand-to-hand, transthoracic flow (2). Neurologic

symptoms may be delayed for up to 2 years and may include ascending paralysis, amyotrophic lateral sclerosis, transverse myelitis, and incomplete cord transection (6).

Blood is an excellent conductor of current, resulting in extensive vascular damage. Electrical injuries damage the intima and media of the vessel walls and form thrombi in the blood. Both lead to vessel narrowing, ischemia, and necrosis. Smaller vessels are more sensitive, with their smaller diameter and inherent higher resistance and heat generation. Coagulation necrosis, disseminated intravascular coagulation, and delayed vessel rupture can occur (9). Arterial insufficiency and compartment syndrome may occur.

Muscle injury occurs through direct heat damage, ischemia from injured blood vessels, and direct electrical injury (8). Direct heat damage causes rhabdomyolysis, which can also lead to acute renal failure. Edema and vascular insufficiency can cause a compartment syndrome. Electrically induced tetanic contractions or secondary blunt trauma can cause dislocations and fractures, including long bone, vertebral compression, and scapular fractures and shoulder dislocations (8).

Injuries to skin can range from asymptomatic lesions to extensive thermal damage. The upper extremities are common locations for entrance wounds, and although the exit site is variable, it is usually the point nearest to the ground or where the electrical circuit can easiest complete. Injuries at these entrance/exit sites usually have erythema, charring, and edema. The skin can also suffer “flash burns” from electrical arc production, electrothermal burns from electrical conduction, and flame burns from ignition of clothing (2).

Of particular concern are oral burns in young children who may chew on an electrical cord. The mucosa of the mouth has a very low resistance and the current arcs through the lip. This can cause a full thickness burn of the lip with involvement of the mucosa, submucosa, muscle, nerves, and blood vessels (2). The resultant eschar usually falls off in 2 to 3 weeks and can be associated with significant labial artery bleeding.

Gastrointestinal (GI) tract involvement includes nausea and vomiting found in 25% and gastric stress ulcers in 13% of electrical

injuries (8). Solid organ injuries may result from associated blunt trauma. Paralytic ileus, hepatic and pancreatic necrosis, and bowel perforation can occur from direct electrical injury.

Direct pulmonary injury is rare given the poor conductivity of air. Direct injury to the respiratory drive center can cause respiratory arrest, although diaphragmatic tetany can also lead to respiratory paralysis. Associated blunt trauma can cause rib fractures, hemothoraces, and pneumothoraces.

Although infrequent, cataracts, vitreous and anterior chamber hemorrhage, retinal detachment, macular laceration, and central retinal artery occlusion can occur (8). Glaucoma is more common in those who survive electrical injuries. Irritation of the anterior chamber can cause miosis, Horner syndrome, or mydriasis. This mydriasis can be mistaken as a fixed pupil, leading to early termination of resuscitation efforts. Rupture of the eardrum is frequently associated with lightning injuries.

Pregnant patients may be completely asymptomatic yet the fetus may suffer significant morbidity and mortality, as the amniotic fluid is an ideal current conductor. Conduction of this current can cause fetal cardiac arrest and abortion.

DIFFERENTIAL DIAGNOSIS

The diagnosis of electrical injury is frequently apparent from the initial history. The real challenge is differentiating between damage caused by direct electrical damage and that caused by associated thermal injuries. Electrical sources of thermal injury include electrical arc, flash burns, and ignition of surface clothing. The diagnosis of these thermal burns is relatively straightforward as the extent of the injury can be judged from the signs of external injury (Chapter 46). The extent of electrical injuries, however, can be very difficult, as the degree of external injury can underestimate the true extent of damage.

ED EVALUATION

Low-voltage exposure will not destabilize patients and local evaluation will be adequate. Prehospital rescuers of high-voltage victims making certain that they do not become victims, must secure the electrical source before intervening. Blunt trauma is common and cervical spine precautions implemented. Patients who are struck by lightning do not retain a static charge and can receive immediate care. Standard advanced cardiac life-support (ACLS) protocols should be followed, and all patients should be transported since many apparently deceased patients have had recovery after high-voltage injury.

All patients with high-voltage injuries should be approached as if they may have multisystem failure and concomitant trauma. Airway, breathing, and circulation (ABCs) should be immediately assessed on arrival and treated appropriately. The patient must be completely exposed to discover evidence of any secondary blunt trauma or burns. Cervical spine precautions should be maintained and imaged as needed to exclude cervical fracture. Cardiac monitoring, pulse oximetry, and supplemental oxygen as needed, should be started. The patient should be questioned about the voltage, type (AC vs. DC), duration, and presumed pathway of the current.

Laboratory studies can help determine the extent of injury. An electrocardiogram (ECG) is indicated for all high-voltage injuries, especially for cases of transthoracic injury (10). A complete blood count, arterial blood gas, coagulation studies, serum electrolytes, calcium, creatine, blood urea nitrogen (BUN), liver function tests, and urinalysis, including urine myoglobin, should be obtained in patients with high-voltage injuries. Cardiac enzymes, including isozymes, and a type and cross should be considered. Vascular and nerve function should be tested to exclude a compartment syndrome. Ophthalmologic and otologic evaluation should look for cataracts and tympanic injuries. Serial laboratory testing of electrolytes, liver function tests, creatinine, BUN, and calcium may be needed to assess ongoing tissue necrosis and injury.

After a Taser incident, patients should be evaluated for their initial agitation, such as a psychiatric condition or drug intoxication,

which may have instigated the use of the device. Most patients will be calm and cooperative by the time of their arrival in the ED. Barbs do not penetrate deep enough to cause significant local injury to most tissues and can be carefully removed.

KEY TESTING

- ECG, cardiac enzymes, and myoglobin for high-voltage injuries
- Complete blood count, blood gas, coagulation studies, metabolic panel, liver function tests for supportive care
- Radiographic imaging for suspected secondary trauma

ED MANAGEMENT

Low-voltage and household electrical injury only requires local evaluation and local care. For high-voltage injury, general supportive care includes management of the ABCs, and advanced cardiac and trauma life support. Cervical spine immobilization should be maintained until fracture is excluded. Cardiopulmonary resuscitation should be initiated in the prehospital setting for nonperfusing dysrhythmias, and resuscitative efforts should be maintained for extended periods of time since many electrically injured, apparently dead patients have been successfully resuscitated (8).

Cutaneous injury from high-voltage exposure does not correlate with tissue injury and extensive internal damage with shock can require aggressive hydration through large-bore intravenous (IV) catheters or central access catheters. Brisk urine output should be maintained to reduce the likelihood of acute renal failure from rhabdomyolysis. Mannitol (1 g/kg IV) should be utilized if urine output is $<$50 to 100 mL/hr in adults or if dark/pigmented urine is noted. Bicarbonate therapy (1 to 2 mEq/kg IV) should also be initiated for any cases where rhabdomyolysis is suspected; the arterial pH should be kept at more than 7 (3,8).

Nasogastric decompression will aid in cases of ileus and help to decompress the GI tract. Prophylactic H_2-blocker therapy is

warranted to prevent stress ulceration. Tetanus status should be updated as needed.

CRITICAL INTERVENTIONS

- Consider the potential for rhabdomyolysis in all but the smallest burns.
- Admit patients for cardiac monitoring when the patient has experienced a loss of consciousness, has a transthoracic injury pattern, or shows signs of dysrhythmia or external injury.
- Provide adequate hydration to reduce the risk of renal failure from rhabdomyolysis.
- Ensure adequate follow-up for children at risk for labial artery bleeding.

DISPOSITION

Loss of consciousness, possible compartment syndrome, and high-voltage injuries should be admitted for observation with possible transfer to a regional burn center. Cases of dysrhythmia, abnormal ECG, signs of myocardial injury, or transthoracic injuries should have 24-hour cardiac monitoring and serial cardiac enzymes (6,10). All cases of rhabdomyolysis warrant admission for treatment to reduce the chance of acute renal failure.

Most low-voltage injuries may be discharged, assuming the patient has not had a loss of consciousness, cardiac dysrhythmia, or tissue damage and a thorough ED evaluation has not found evidence of internal injury. Children with oral injury from chewing on electrical cords require special instruction and follow-up for delayed hemorrhage from labial artery bleeding when the eschar sloughs off. Discharge only those patients with reliable follow-up; admit all questionable cases.

Common Pitfalls

- Failing to recognize that surface injury does not correlate with the extent of internal injury.

- Putting the rescuer at risk by trying to remove a patient from an electrical source before stopping the current.
- Failing to examine all patients for compartment syndrome in cases where neurovascular compromise is suspect.

CHAPTER 365

Lightning Injuries

N. Stuart Harris and David F.M. Brown

Lightning injuries are second only to flooding as the leading cause of weather-related death in the United States (1,4). Lightning is responsible for 75 to 100 deaths per year and as many as 1,000 injuries (1,4). The incidence of lightning injuries parallels the frequency of thunderstorms, with clear seasonal (summer) and daily (afternoon) variations. Victims are most often those who work or play outdoors and are predominantly male (4,8). Although frequent thunderstorms make the Gulf Coast States a leading site of lightning injury, states with major mountain ranges and tidal river basins are also at increased risk (1,8).

Electrical charges in clouds are produced by the movement of ice particles in convective currents, which create a layering of ionic charges: the uppermost cloud gains a net positive charge, and the bottom of the cloud gains a net negative charge (3). The cloud's negative charge gathers positively charged particles along the ground, creating a large potential difference. Eventually this potential difference becomes so great that the atmosphere's electrical resistance is overcome and an ionized plasma channel forms. This ionized channel advances from the cloud towards the earth in a downward-branching "stepped leader" pattern at 1/1,000th to 1/2,000th the speed of light. As the stepped leader pattern nears the ground, a "return stroke" ascends from the ground at about one-tenth the speed of light, completing the plasma channel between the cloud and the ground. The channel is now complete, and a massive transfer of electrical charge occurs,

producing an instantaneous brightening of the ionized pathway (the visible lightning flash) (3).

Thunder results from the rapid expansion of warmed air and the air's subsequent contraction and implosion. Although not technically accurate, lightning behaves physiologically as direct current, with an energy level of 2,000 to 2 billion V and 2,000 to 300,000 A (4,8). Although lightning's voltage and amperage are much higher than conventional electricity, the extremely short duration of lightning contact (0.1 to 1 milliseconds) usually limits cutaneous penetration and commensurate deep tissue injury (4,8). Except for direct strikes, most of the lightning current is thought to "flash over" the outside of the victim, with a relatively limited amount of current leaking internally to interfere with cardiac automaticity, respiratory center function, and autonomic stability (4,8).

There are several major mechanisms of lightning injury. A direct strike occurs when the major pathway of current runs directly through the victim; this results in the highest morbidity and mortality (4,8). When the lightning current strikes an object in contact with the victim, the injury mechanism approximates a direct strike. With "side splash," current arcs from an object through the air to the victim. "Ground current," also known as "ground potential," occurs when lightning strikes the ground and spreads to involve the victim. If ground resistance is greater than the victim's resistance, current may enter one leg and exit through the other (3). Ground current and side-flash mechanisms are capable of producing multiple casualties.

Associated trauma should be expected and may result from a variety of mechanisms: myotonic extremity or neck contractions, blunt or penetrating injuries from debris or fall, and thermal burns potentially exacerbated by metal jewelry or caused by ignition of clothing.

CLINICAL PRESENTATION

Because of the short duration of lightning exposure, current usually passes over the outside of the body ("flashover" phenomenon),

commonly producing superficial or partial-thickness burns (4,8). Pathognomonic fern-like, erythematous patterns known as Lichtenberg figures may be observed (4). Entry and exit wounds and deep internal burns with resultant rhabdomyolysis and myoglobinuria are rare.

The most common cause of death in the lightning victim is cardiopulmonary arrest (CPA) (3,4,8). Internal propagation of the lightning's electrical potential acts as a massive direct current counter shock, which depolarizes the entire myocardium and causes cardiac asystole (3,4). As a result of cardiac automaticity, an organized electrical rhythm may re-emerge, restoring spontaneous circulation (4). However, primary respiratory arrest as a result of lightning-induced paralysis of the medullary center may occur concomitantly and can outlast cardiac arrest (CA) (3,4,8). Without prompt and prolonged ventilatory support, any return of cardiac rhythm and circulation is likely to deteriorate to hypoxia-induced ventricular fibrillation (3,4). Survivors of lightning exposure can exhibit a variety of cardiac abnormalities, with dysrhythmias and ST–T-wave changes frequently reported (4,7). Acute life-threatening (and often reversible) left-ventricular dysfunction or pericardial tamponade, as demonstrated by echocardiography, has been reported (6,7).

A variety of neurologic effects of lightning injury are frequently encountered. Complete loss of consciousness is common (2,9). In the absence of CPA, consciousness eventually returns, occasionally after a prolonged period. Other common findings include paraplegia, hemiparesis, hemiplegia, localizing sensory deficits, and autonomic dysfunction (2,8,9). The extremities may initially appear cold, mottled, pulseless, and insensitive secondary to vascular spasm and autonomic instability: a phenomenon known as keraunoparalysis (2,4,8). This vasospasm should not be treated with interventions beyond supportive measures.

Virtually all lightning-struck patients have altered mental status and anterograde amnesia; retrograde amnesia is common as well (2,3,4,9). Persistent neuropsychologic, cognitive, and behavioral abnormalities are commonly found (2,8). Intracranial hemorrhage

(particularly in the basal ganglia and brainstem), epidural and subdural hematomas, coagulation of brain parenchyma, and thrombosis of vessels have been described (2,3,8,9). Associated trauma may cause cervical spine fracture with spinal cord injury.

Half of patients with lightning injuries have ocular sequelae (4,8). Cataracts are common and may develop in a few days or up to several years after the injury (4,8). Corneal lesions are also common; hyphema, iritis, vitreous hemorrhage, retinal detachment, and optic nerve injury have been described (4,8). Unreactive, dilated pupil(s) as a result of transient autonomic instability may occur and should not be mistaken for a sign of brain death (2,3,8,9).

Tympanic membrane rupture, the most common otologic injury, occurs in 50% of victims of lightning injury and is probably a result of the shock wave of expanding hot air (thunder) during the strike (3,9). Less common findings are hemotympanum, basilar skull fracture, and various acoustic and vestibular sensorineural deficits (4,8,9).

DIFFERENTIAL DIAGNOSIS

Lightning injuries may mimic a range of potentially life-threatening diseases. Neurologic disease processes that can mimic lightning injury include cerebrovascular accidents, seizure disorders, and craniocerebral, spinal cord, or other neurologic trauma (4). Cardiovascular disorders in the differential diagnosis of lightning injury include myocardial infarction, Stokes–Adams attacks, and cardiac dysrhythmias (4,8). The differential should also include toxic ingestions, envenomations, and physical assault. Cutaneous injuries may be misdiagnosed as electrical burns.

As in most clinical situations, the history is crucial to making the correct diagnosis. Obtaining information from bystanders is essential when the victim is incapacitated. Important points include a history of thunderstorm and outdoor occurrence of the accident. Physical examination findings of the arborescent erythematous pattern of Lichtenberg figures are pathognomonic. Tympanic membrane rupture is also highly suggestive.

ED EVALUATION

The history should include a description of events at the scene of injury. Any prehospital interventions and their times should be documented. Present complaints and medical history prior to presentation should also be noted.

The physical examination should focus initially on vital signs; assessment of the airway, breathing, and circulation; and evaluation for trauma and neurologic dysfunction. Serial neurovascular examinations should be performed in patients with signs of peripheral vascular insufficiency. All patients should initially have cardiac monitoring, an electrocardiogram (ECG), and oxygen saturation measurement. Laboratory evaluation can include a complete blood count, serum electrolytes, blood urea nitrogen, creatinine, glucose, and creatine phosphokinase. Urine should be tested for myoglobin. Patients with cardiac dysrhythmias or ischemia, respiratory arrest, or loss of consciousness should have a chest radiograph and cardiac biomarker analysis. Cervical spine radiographs and a cranial computed tomography (CT) scan might be helpful with altered mental status or neurologic deficits. Other radiographs and tests should be obtained as indicated by the history or physical findings.

KEY TESTING

- For all patients: cardiac monitoring, an ECG, and oxygen saturation measurement. Laboratory evaluation should include a complete blood count, serum electrolytes, blood urea nitrogen, creatinine, glucose, and creatine phosphokinase. Urine should be tested for myoglobin.
- For patients with cardiac dysrhythmias or ischemia, respiratory arrest, chest pain, or loss of consciousness: Obtain chest radiograph and cardiac biomarker analysis.
- For patients with altered mental status or neurologic deficits: Consider cervical spine radiographs and a cranial CT scan.

ED MANAGEMENT

Prehospital care of victims with lightning injuries may place initial responders at risk of lightning strike (10). Although acute medical intervention is paramount to reduce mortality, care should be taken to prevent harm to rescuers. Once scene safety has been assured, management should begin with assessment and stabilization of the airway, ventilation, and circulation (10,11). Victims should be treated as trauma patients, with special attention given to cervical spine immobilization. In a mass-casualty event, "reverse triage" should be employed. In a reversal of the usual dictum, rescuers should focus initially on victims in CPA (3,4,8,10,11) because virtually all victims of lightning strike who do not suffer CPA or respiratory arrest survive (4). Standard advanced life-support (ACLS and ATLS) protocols are appropriate however, and aggressive, persistent resuscitative efforts are indicated for all victims, especially those with spontaneous cardiac rhythms and prolonged apnea or coma (4,8,10,11). Ventilatory support may be required for several hours, but, even in these cases, there is potential for full recovery (4,8). Full support should be continued until cerebral function can be assessed.

All patients should initially be given supplemental oxygen, should have intravenous access established, and should be placed on a cardiac monitor. Intravenous fluids should be minimized to reduce any risk of cerebral edema unless hemorrhage, hypotension, or dehydration is evident or rhabdomyolysis is a concern (e.g., with deep or extensive burns or associated crush injury). Although not common, rhabdomyolysis, as indicated by myoglobinuria and elevated serum muscle enzyme levels, may necessitate fluid loading, osmotic diuresis, and urine alkalinization. Standard burn and wound care and tetanus prophylaxis should be given, if appropriate. Patients with cardiac or neurologic abnormalities should have serial ECGs, cardiac biomarker analyses, and routine supportive care. All patients require comprehensive and repeated physical and neurologic examinations.

CRITICAL INTERVENTIONS

- Reverse triage. In a mass-casualty incident involving lightning injury, give the highest priority to patients in cardiac or respiratory arrest when making triage decisions.
- Institute advanced cardiac support measures, and make a prolonged effort to resuscitate patients found pulseless or apneic after a lightning strike.
- Evaluate patients struck by lightning for traumatic injuries.
- Treat keraunoparalysis (cool, potentially pulseless, or numb extremities) conservatively with supportive care.

DISPOSITION

Patients with suspected direct strike or those with cardiac or neurologic abnormalities require admission for at least 24 to 36 hours of observation and continuous cardiac monitoring. Those patients with associated trauma, burns, or rhabdomyolysis also may require admission for their injuries (4,8,11). Patients who have sustained cardiac or respiratory arrest should be admitted to an intensive care unit. Long-term follow-up with neuropsychiatric support is recommended for all patients.

The decision to transfer a patient to another facility depends on the severity of injury and the ability of local resources to provide adequate care. If the necessary services are unavailable, the decision and the timing of transfer should be coordinated with the receiving physician at the nearest appropriate hospital. Emergency personnel with advanced life-support (ALS) capability should accompany the patient.

Common Pitfalls

- Failure to appreciate the difference between lightning injuries and high-voltage injuries.
- Misdiagnosing lightning injury as an isolated cutaneous burn or a primary neurologic or cardiovascular event.
- Misinterpreting unreactive, dilated pupils as a sign of death in patients struck by lightning.

- Failure to admit patients with neurologic complaints or deficits for observation.

CHAPTER 366

Radiation Injuries

Joe Suyama

Radiation injuries can arise from a range of potential scenarios ranging from accidental exposure to nuclear power or medical devices, a radiologic dispersion device (RDD), or “dirty bomb,” to the intentional poisoning of an individual.

Radiation is defined as the transfer of energy in the form of waves, rays, or particles. Ionizing radiation originates from the decay of inherently unstable radionuclides and is emitted in the form of α- and β-particles, γ- and x-rays, and neutrons. Positively charged α-particles consist of two neutrons and two protons and do not penetrate further than 0.05 to 0.1 mm into tissue. However, they cause high linear energy transfer (LET) to tissues. Simplistically, the amount of subsequent cellular damage increases with increasing LET. Internalization of α-particles is associated with the potential for significant radiologic damage. Polonium-210 is an example of an α-particle emitter, which must either be inhaled or ingested to be radiotoxic (1). After entering the blood stream, it is deposited in the liver, spleen, bone marrow, and other soft tissues of the reticuloendothelial system, causing death at high enough doses. Negatively charged β-particles are low LET particles with a penetration depth of 5 to 30 mm. γ- and x-rays lack both charge and mass and are low LET rays, but they are highly penetrating. Neutrons lack a charge, are deeply penetrating, and are classified as high LET particles. Neutrons do not ionize tissues directly but rather transfer energy to atoms in the tissues, which then create α- and β-particles, γ- and x-rays, and subsequent tissue effects. Tissue effects are either deterministic, immediate and clinically apparent tissue

damage, or stochastic, which largely refers to the teratogenic effects of radiation (2).

The amount of energy transferred to tissues per unit mass of the target is quantified by the radiation absorbed dose (rad). One hundred rads equals one Gray (Gy). Potential for tissue injury is dependent on both the dose and radiation quality, which refers to varying biologic effects based on LETs. The radiation equivalent in man (rem) reflects the biologic impact of the absorbed radiation dose. The rem is expressed as sieverts (Sv) in SI nomenclature, with 100 rem = 1 Sv, which is now the more widely accepted unit for expressing the health effects of radiation.

Ionizing radiation can produce adverse health effects from both internal and external exposure. Ingestion or inhalation of contaminated materials can cause significant local effects. Incorporation occurs when the body replaces regular components with its radioactive counterpart or similar molecule. Bone and thyroid are particularly prone to the replacement of elements with radionuclides. Radium (Ra-226) and uranium (U-235) accumulate in bone, radioactive iodine (I-131) can replace its nonradioactive isotope in thyroid, and from a more therapeutic and diagnostic perspective, radioactive phosphorus (P-32) can replace phosphorus in a multitude of biochemical processes and structures. Radionuclides that are incorporated are difficult to eliminate and have the potential to produce long-term health effects in addition to acute symptoms. External radiation sources produce local effects from direct skin or clothing contamination or by dosing the entire body with irradiation.

Ionizing radiation initiates a cascade of detrimental chemical reactions by generating free radicals as tissue is energized. Tissue is energized directly by α- and β-particles but γ- and x-rays excite atoms in the tissue by transferring energy to an electron, which subsequently ionizes other molecules in proximity. Although subcellular damage can occur by structural protein or enzyme degradation, the majority of cellular damage and death occurs through disruption of DNA and the mitotic apparatus. The most radiosensitive cells and tissues are those with high turnover rates,

such as hematopoietic, reproductive, gastrointestinal (GI), and epithelial cells. Relatively radiation-resistant tissues include bone, solid organs, muscle, and neuronal tissues.

Radioactive substances can be found in many settings and forms. Radioactive materials are found in medical settings, research facilities, industrial sites, and nuclear power plants (3). Naturally occurring background radiation exposure accounts for 3 to 3.6 mSv per year; this and other radiation doses from medical procedures are listed in Table 366.1. According to the Department of Energy–Radiation Emergency Assistance Center/Training Site (REAC/TS) Radiation Accidents Registry, the majority of radiation accidents occur in the medical, energy production, or industrial settings (4). Current occupational exposure limits for individuals working with radiation sources are 0.05 Sv per year and 5 mSv per year for pregnant women. For the general public, current limits are 1 mSv per year (5).

TABLE 366.1
Dose Ranges from Background Radiation Exposures and Selected Medical Procedures

Radiation Exposure	Dose Range	Body Part Affected
Background radiation	3–3.6 mSv/yr	Total body
Smoking 1 PPD/yr	160 mSv	Respiratory system, body
Transcontinental flight	0.05 mSv	Total body
Diagnostic chest x-ray single view	0.10–0.15 mSv	Collimated field
Diagnostic chest x-ray two view	0.60 mSv	Collimated field
CT head	10 mSv	Head
CT abdomen	20–50 mSv	Abdomen
Fluoroscopy	10 mSv	Collimated field
Bone scan	50 mSv	Total body
Annual exposure limit—public	1 mSv/yr	Total body
Annual exposure limit—occupational	50 mSv/yr	Total body
Annual exposure limit—occupational, pregnant	5 mSv/yr	Total body
LD_{50}	4.5 Sv	Total body

Rem converted to Sv.

Reproduced with permission Frame P. *Radiation fact sheet*. Oak Ridge, TN: Oak Ridge Institute for Science and Education/Oak Ridge Associated Universities; 1995.

Radiation accidents are typically secondary to the improper use of radiation devices and improper use of radioisotopes. Between 1944 and 2002, a total of 428 radiation accidents have been documented worldwide, resulting in 133,815 persons affected and 134 fatalities. Nearly 90% of these victims were the result of the 1986 Chernobyl nuclear reactor accident. More recently, the near-critical event and leakage of radioactive materials from the Fukushima Daiichi plant after the 2011 Great East earthquake and tsunami in Japan reinforced the need to be locally prepared to respond to the immediate and long-term medical needs of the people living in proximity to nuclear facilities and of the emergency responders to radiologic incidents. Other historically important mass-casualty radiation accidents include the rupture of an iridium source in Venezuela; a cobalt-therapy unit accident in Ciudad Juarez, Mexico; and the theft and subsequent large exposure of a cesium source in Goiania, Brazil (4). A comprehensive planning guide to these and other types of radiation events has been produced by the

International Commission on Radiological Protection to assist local medical planning and response and recovery efforts (6).

Individuals and groups may intentionally use radiologic materials for terrorist purposes. Such use may introduce new combinations of radiologic injury, or radiation injury may be misdiagnosed as other routine medical conditions. For example, an RDD may combine blast and radiation injuries and may disperse radioactive substances, creating a contamination hazard for the environment and both real and psychological casualties (7). Initial fatalities from an RDD are anticipated to be minimal and related to blast injuries (8), but the greater threat from the unrecognized radioactivity of RDD detonation is the contamination of receiving facilities. The mysterious death of Alexander Litvinenko in November 2006 from multisystem organ failure was initially difficult to recognize as Polonium-210 ingestion without further specialized diagnostic testing. Finally, direct attacks on nuclear power plants would not yield a nuclear explosion, but intentional meltdown of the core may cause similar environmental and health effects as seen at Chernobyl (9). Such events may not create a large number of immediate casualties, but the public health risk related to carcinogenesis may be significant over time. The greatest impact may be the fear and uncertainty that follows these events.

CLINICAL PRESENTATION

Acute radiation injury to the skin and underlying structures causes changes that clinically resemble thermal burns, with desquamation and blistering. Unlike thermal burns, these signs develop after a period of at least 48 to 72 hours after the contact. The clinical effects of dermal radiation exposure are listed in Table 366.2. Delayed skin effects include carcinogenesis, vascular insufficiency, and chronic nonhealing ulcers.

TABLE 366.2
Cutaneous Manifestations of Radiation Exposure

Cutaneous Effect	Radiation Dose Threshold (Sv)
Early transient erythema	2
Temporary epilation	3
Prolonged erythema	6
Dry desquamation	10
Moist desquamation	20
Tissue necrosis	20–30

Whole-body radiation exposure clinically manifests as acute radiation sickness (ARS), a progression of systemic effects from derangements of the hematopoietic, GI, and neurologic systems. ARS has four general phases: (1) prodromal, (2) latent, (3) illness, and (4) recovery or death. Depending on the dose rate and total absorbed dose, ARS may progress rapidly to death or be completely asymptomatic (Table 366.3). Larger total-body doses correlate with increasing severity of symptoms and decreasing time interval to onset (10). The prodromal phase usually lasts 48 to 72 hours and manifests as nausea, vomiting, diarrhea, and nonspecific constitutional symptoms. The latent phase, which may last 3 weeks, is characterized by the lack of clinical symptoms and apparent recovery from the prodromal phase (7). The latent phase is followed by the illness or hematopoietic syndrome, in which initial damage to the bone marrow becomes clinically apparent. Pancytopenia and the subsequent sequelae of immunosuppression, bleeding diathesis, and anemia often lead to death from sepsis unless adequately supported. If the patient survives the illness phase, which lasts up to 30 days postexposure, recovery occurs 3 to 6 weeks after initial exposure.

TABLE 366.3
Acute Radiation Syndrome and Dose-Related Effects

Whole-Body Dose (Gy)	Effect
0.05–0.5	No clinical symptoms, minor lymphocyte reductions, potential chromosomal damage
1	Nausea and vomiting within 48 hrs of exposure (10% of patients)
2	Nausea and vomiting within 24 hrs of exposure (50% of patients), prominent decreases in lymphocytes and granulocytes
4	Nausea and vomiting within 12 hrs of exposure (90% of patients), mortality of 50% without medical support
6	Mortality of 100% within 30 d without medical support
10	Maximum survivable dose with aggressive medical support
50–100	CNS and cardiovascular collapse within 24–48 hrs, mortality of 100%

Patients receiving total body doses in excess of 7 Sv manifest a distinct entity referred to as the GI syndrome, in addition to the prodromal symptoms (Table 366.4). The GI syndrome results in significant fluid and electrolyte losses, loss of bowel integrity to enteric bacteria, and subsequent death in more than 80% of patients. A pulmonary syndrome is noted at doses of 5 to 10 Sv, manifesting as pneumonitis, respiratory failure, and subsequent pulmonary fibrosis and cor pulmonale. Patients with total-body doses of 9 to 17 Sv develop a cerebrovascular syndrome, and patients receiving more than 50 Sv develop acute encephalopathy, with rapid (hours to days) progression of cerebral edema, cardiovascular collapse, and 100% mortality.

TABLE 366.4
Acute Radiation Syndrome: Symptoms and Radiation Dose

Symptoms	Radiation Dose (Gy)
Prodromal symptoms	
Anorexia	1
Nausea	1.4
Vomiting	1.8
Diarrhea	2.3
Hematopoietic syndrome	2–4.5
Pulmonary syndrome	5–10
Gastrointestinal (GI) syndrome	7–15
Cerebrovascular syndrome	9–17
Acute encephalopathy	50–100

DIFFERENTIAL DIAGNOSIS

Early symptoms of nausea and vomiting are nonspecific, resembling gastroenteritis or food poisoning. Lymphopenia, immunosuppression, and anemia are not only characteristics of radiation sickness but also can be manifestations of HIV and other viral infections, leukemia, use of chemotherapeutic agents, toxic ingestions, and blood dyscrasias.

The differential diagnosis of radiation-induced dermal injury includes chemical, ultraviolet and thermal burns. In contrast to these entities, radiation-associated dermal injury is typically delayed up to 2 weeks. Other dermal lesions to consider include bullous pemphigoid, necrotic arachnidism, and stasis ulcers.

Concomitant radiation contamination should be suspected in any potential terrorist event. Although extraordinarily large doses of radiation can cause rapidly progressive shock, radiation typically does not cause sudden death. It is also unlikely to cause the immediate incapacitation of large numbers of people resulting from weapons of mass destruction incident. Other agents should be suspected should such scenarios arise.

ED EVALUATION

Because of the extreme rarity and potential calamity of an unexpected radiation exposure, the Joint Commission requires that every hospital develop a formal plan to deal with such an event.

Prudence also dictates that every regional emergency management system includes radiation accidents in its disaster management protocol. Specific prehospital management guidelines have been developed by REAC/TS, and are available online at http://www.orau.gov/reacts/manage.htm.

When notified that a radiation accident may have occurred in which many people were exposed to high levels of radiation, the physician should invoke the hospital and regional plans, following them as closely as the circumstances of the particular incident allow. The hospital's radiation safety officer, and the radiation safety officer employed at the site of the accident (or at the company whose truck has crashed, for instance), must be contacted immediately. Police and fire authorities and a public relations official should be called. The physician should communicate with the scene while the area designated in the hospital to receive patients is prepared. Specialized radiation detectors can be used in emergency departments (EDs) to identify patients who are emitting radiation from nonmedical radionuclides that should not be present in a healthcare environment. Such devices help to filter out the noise of the background medicinal and diagnostic radionuclides typically present in hospitals, and can provide an early warning of the presence of inappropriate radiation contamination (11).

It must be determined exactly what sort of accident has happened: an exposure to external radiation, contamination by radioactive matter, or possible incorporation of ionizing substances via open wounds or the GI or respiratory tracts. A history of trauma or other toxic exposures and the nature, severity, and time of onset of any symptoms should be noted. The duration of exposure (partial or whole body), the nature of and distance from the source, and shielding and dosimeters used, if any, all constitute important data.

Patients require careful evaluation by a designated radiologic emergency response team to minimize contamination of the ED (12). When possible, arriving patients should be undressed in the ambulance, and clothes should be collected, bagged, and stored at a point distant from the patient care areas. A designated receiving area large enough to manage the anticipated number of casualties

should be established. The decontamination area should be prepared and ready for use for both ambulatory and nonambulatory patients. Areas that are likely to be traversed by contaminated patients and workers should be cordoned off. Paper or plastic sheets should be placed on the floor. Entry points to the radiation treatment areas need to be staffed by radiation officers trained to scan for contamination as workers exit the radiation treatment area, and large numbers of gloves, boots, gowns, and masks need to be available for workers entering the area. Strict isolation and double-bagging procedures should be maintained, and a buffer zone should be established for additional contamination control. No special ventilation controls are currently recommended.

All care providers must wear barrier protection, masks, and eye protection to prevent internal and external contamination. Furthermore, four ALARA (As Low As Reasonably Achievable) principles provide the foundation for radiation protection: timing, distance, shielding, and quantity. For timing, all personnel must wear a radiation detector to determine the whole body dose accumulated during patient contact. Personal dosimeters with real-time displays are preferred over radiation badges to limit any unnecessary exposure and to determine when to rotate teams of care providers. For routine procedures and care, teams should be rotated once 5 rem have been accumulated. The upper limit to provide lifesaving interventions must be predetermined by the radiation safety officer. For those performing lifesaving interventions, the recommended limits for total effective dose range from 0.25 to 1.5 Sv, or a rate of exposure $\leq$0.1 mGy/hr, depending on the radiation organization cited (13). For simplicity, a total-body exposure of 0.5 Sv is the National Council of Radiation Protection and Measurements/International Council of Radiation Protection and Measurements (NCRP/ICRP) recommended dose acceptable for preserving life (5). Workers in this setting should be volunteers chosen on the basis of age (older) and lowest accumulated lifetime effective doses.

Distance from a radiation source should be maximized when feasible, because the exposure dose decreases in proportion to the

square of the distance from the source. Shielding high-density materials such as lead or concrete provides greater relative levels of protection from ionizing radiation than do less dense materials. Most structural elements (e.g., walls, floors, etc.) and personal protective equipment (PPE) will not block high-energy γ-rays. PPE will, however, provide a physical barrier to contamination from radioactive fallout and debris from RDDs. PPE is also effective in blocking the effects of α-particles and a proportion of β-particles as well. The quantity of ionizing radiation can also be limited by removing the radioactive source material from the area.

If no life-threatening illness is present, a rapid survey of patients using a "pancake" detector or a GM counter should be performed. Ideally, survey meters capable of detecting both high-range (up to 5 Sv/hr) and low-range (up to 0.2 Sv/hr) exposures and also common (γ and β) or uncommon (α and neutron) sources should be available. The initial scan should progress rapidly from head to toe, focusing on any open wounds or obvious debris. For the ambulatory patient, the survey should focus on areas, such as the hair and shoulders, where fallout generally accumulates. If the patient is unstable, critical interventions should be performed in conjunction with the radiation survey (14).

Anatomic charts should be used to document the location of all radiation emission and the radiation counts. Example charts and forms can be downloaded from http://www.afrri.usuhs.mil/www/outreach/pdf/afrriform331.pdf. Samples with cotton swabs should be taken of all orifices if external contamination is suspected. The physical examination should include evaluation for concomitant trauma. In all cases of radiation injury, a complete blood count and differential, a type and screen, and serum electrolytes and urinalysis should be obtained to determine kidney function. Subsequent investigations are driven by the patient's clinical presentation.

KEY TESTING

- A CBC with differential count should be obtained for the purposes of identifying the absolute lymphocyte count and should be interpreted in the context of the temporal relationship to the radiation injury.
- Trauma laboratory work and imaging should be performed as warranted, and should be performed in conjunction with decontamination.
- Radiation dosimetry should be attempted, and initial and persistent contamination severity and the affected anatomical areas should be documented with a portable GM counter.
- Radiation spectrometry can be performed to determine if radiation sources are typical hospital radioisotopes or are nonmedicinal in nature.
- Biologic samples and fluids should be obtained and stored for analysis by radiation safety and health physics consultants.

ED MANAGEMENT

The organized delivery of care to radiation-injured patients can increase the survival of those with whole-body radiation injury (4). A tremendous amount of information and relevant protocols for the ED management of radiation injuries can be found on the REMM website: http://www.remm.nlm.gov. ED management of radiation injuries is summarized here, starting with initial contact and decontamination procedures (6,12,15).

Decontamination procedures begin with the removal of all clothing. This eliminates 80% to 90% of external contamination. Because radioactive debris may remain in the hair after removal of grossly contaminated clothing, surgical caps should be placed on the unstable contaminated patient to provide some limited shielding and contamination containment to protect staff while performing advanced life-support procedures. All clothes, debris, and bandages must be properly stored. The hospital radiation safety officer must properly dispose of the waste once surveyed. When contaminated debris or shrapnel are removed from patients, they should be placed

in appropriate lead-shielded containers and removed from patient-care areas.

Wounds should be decontaminated aggressively, then treated as usual and covered with plastic and tape prior to decontamination of intact skin. External decontamination should proceed from the area with the most debris to the area with least. Uncontaminated areas should also be covered and taped. Using tepid water and mild soap or nonionic detergent, very gentle scrubbing should be done for 3 minutes with the patient lying either on a special decontamination table (similar to an autopsy table) or on a makeshift plastic trough placed on a stretcher in slight reverse Trendelenburg. Hot water should be avoided because it causes capillary vasodilation and raises the potential for increased radionuclide absorption. Aggressive scrubbing should likewise be avoided because of the potential for abrasions that can increase dermal absorption. This procedure should be repeated with serial radioactive screening and continued as long as counts are decreasing. Gentle brushing under nails, in hard to clean areas such as between fingers, axilla, groin, of skin folds, hair and clipping of hair, including body hair (not shaving, which might leave small open wounds) may be required. All fluids should be collected if possible. If the patient is stable, decontamination attempts can stop when the radioactivity level cannot be further reduced with serial GM counter testing.

Most isolated radiation injuries are not medical emergencies and only require supportive care, baseline laboratory testing, and follow-up for specialty care such as burns, infectious disease, and hematology/oncology. Specific antidotes and chelation agents are available that may assist in mitigating the effects of the radionuclide burden from internally contaminated patients. These agents do so by decreasing the overall radionuclide burden by dilution, displacement, blockage, or chelation. However, it is difficult to differentiate between radionuclides without scintillators or other advanced laboratory equipment that is found only in select laboratory settings. If identification is possible or a likely radionuclide is suspected from the type of radiation accident, antidotes must be administered promptly or the effectiveness will be

limited. There are several tools, such as the Biological Assessment Tool (available at the Armed Forces Radiobiology Research Institute website: http://www.afrri.usuhs.mil) and the Radiation Injury Severity Classification (RISC) system, that can help the clinician determine the total whole-body radiation delivered based upon clinical symptoms (biologic dosimetry) alone (16).

Treatment of ingestions should begin with attempts to decrease the chance of internal irradiation or incorporation. Whole-bowel irrigation, using a polyethylene glycol bowel prep solution (e.g., GoLYTELY, Colyte) at 0.5 to 2 L/hr until the rectal effluent is clear, may be beneficial. Activated charcoal is also recommended. Washings should be saved, surveyed, and disposed of by the radiation safety officer. Bronchoalveolar lavage may be helpful if stained or radioactive sputum confirm that radioactive dust has been inhaled.

Specific therapy for radiation injury includes medical countermeasures, prophylaxis, and supportive care. There are specific medical countermeasures for certain radionuclides, such as Prussian blue for thallium, cesium, or rubidium; and barium sulfate or aluminum-based antacids for radium or strontium. Prussian blue (Radiogardase) works by increasing fecal elimination of the radionuclide. Prussian blue is taken orally and will not compete with other treatment agents such as oral potassium iodide (KI). Clinical side effects include constipation and GI upset. Prussian blue is most effective when administered soon after exposure but should be administered as soon as cesium or thallium has been identified as the radionuclide in question. In the Goiania incident involving cesium, Prussian blue at doses ranging from 3 to 10 g/day resulted in a 71% reduction in mean dose (3).

Potassium iodide (KI) should be administered to those in whom exposure to iodine-131 (I-131) is likely (18). Such events include an RDD contaminated with medical I-131, release of radioisotopes from a nuclear reactor, and nuclear detonation. Children may benefit most from the protective effects of KI AsKI works by competition to prevent the incorporation of radioactive iodine by the thyroid gland, the maximum benefit is conferred when KI is administered before

exposure to I-131. It will protect the thyroid from increased risk for cancer but will not mitigate any other forms of acute or long-term radiation effects. The dose of KI is approximately 2 mg/kg. The protective effects of KI last approximately 24 hours, and daily dosing for up to 2 weeks, is usually at the discretion of the local health department. Short-term treatment of KI at thyroid-blocking doses is safe, although side effects of sialadenitis, GI upset, rashes, and allergic reactions are most common. As internal contamination of radioiodine will partition into breast milk, lactating mothers should not breastfeed their infants until public health authorities have deemed it safe to consume the milk.

Other countermeasures include pentetate calcium trisodium injection (Ca-DTPA) and pentetate zinc trisodium injection (Zn-DTPA). Both agents are now approved by the US Food and Drug Administration (FDA) to treat internal contamination with plutonium, americium, or curium (17). For specific conditions relating to ARS, such as the hematopoietic syndrome, use of hematopoietic colony–stimulating factors may enhance neutrophilic recovery by increasing the absolute numbers of white blood cells and decreasing the period of neutropenia (20).

Supportive care is needed for ARS, for medical and surgical comorbidities, and for psychological trauma. The initial management of concomitant trauma is the same as for other patients. Wound healing is adversely affected by radiation, and the likelihood of infection is increased due to fibroblast damage, bleeding diathesis, and loss of bone marrow that occurs over time. In light of this, definitive surgery should be performed within the first 48 hours of exposure. Otherwise, nonemergent procedures such as internal fixation of fractures is best delayed at least 3 to 60 days until bone marrow production returns to normal (19). Prophylaxis against bacterial infection in neutropenic patients may require empiric antibiotic therapy, specifically with antipseudomonal agents.

Children may have greater health effects with regard to radiation injury. Children are more metabolically active, and have potential greater risks for both deterministic and stochastic effects. They are

also more likely to incorporate radioisotopes by ingestion or inhalation. Although psychological support is necessary for all patients, the pediatric population may be particularly susceptible to long-term psychological sequelae from real or suspected radiation injury (21).

During the UK Health Protection Agency investigation of the death of Alexander Litvinenko, approximately 596 individuals tested positive for polonium-210 (22), although only 13 were found to have had significant exposures. However, fears of polonium-210 contamination led thousands to seek medical attention. Physical manifestations of acute stress reaction, including nausea, vomiting, and vague constitutional complaints, can mimic those of acute radiation syndrome and can complicate the appropriate disposition of these patients (20,23).

CRITICAL INTERVENTIONS

- Notify the hospital radiation safety officer and activate the hospital radiation exposure plan for patients with possible radionuclide contamination.
- Use time, distance, shielding, and quantity-reduction techniques to minimize exposure.
- Wear barrier protection, masks, eye protection, and dosimeter, if available.
- Perform resuscitation and stabilization as necessary.
- Perform external and internal decontamination and isolate and remove contaminated clothes, debris, and fluids.

DISPOSITION

After initial ED management, patients may be discharged for outpatient management depending on extent of prodromal symptoms and absolute lymphocyte count at presentation. Onset of prodromal ARS symptoms <30 minutes after exposure indicates a total-body dose >6 Sv, although onset >2 hours after exposure indicates a dose <2 Sv. Onset of prodromal symptoms more than 24 hours after exposure indicates a dose <0.7 Sv (Table 366.4) (15).

Severe nausea and vomiting indicate a substantial whole-body dose, (i.e., 2 to 10 Gy) that will require inpatient monitoring for supportive care.

The lymphocyte count is routinely used to aid in disposition and management of radiation injuries. If the patient is asymptomatic and has a normal lymphocyte count, early follow-up and frequent complete blood counts may be appropriate. Prognosis is directly tied to the 48-hour lymphocyte count, which is dose-dependent (Table 366.5). Lymphocyte counts >1,200/μL indicate a good prognosis, and counts <300/μL indicate a poor prognosis (24). Individuals with total-body doses >10 Sv will likely need admission, and those with doses >30 Sv may require reverse isolation precautions.

TABLE 366.5
Relationship Between Absolute Lymphocyte Count and Outcome After Total-Body Radiation Exposure

Outcome	Lymphocyte Count/ mm^3 at 24 hrs	Lymphocyte Count/ mm^3 at 48 hrs
Normal	1,750	>1,500
Moderate injury	1,500	1,000–1,500
Severe injury	1,000	500–1,000
Very severe injury	500	100–500
Lethal	<100	<100

Hematology consultation will be required to administer growth-factor therapy and colony-stimulating factors, treat anemia and thrombocytopenia, and provide advanced cytokine therapy or cord/placental-blood progenitor cells. Burn, infectious disease, and bone marrow transplant consultation may also be necessary (25).

Questions regarding radiation accidents and exposures can be referred to the US Department of Energy through the REAC/TS, Oak Ridge, TN, by the web, http://www.orau.gov/reacts, or by phone, 865-576-1005. Other online references include the Radiation Event Medical Management website (http://www.remm.nlm.gov) hosted by the Department of Health and Human Services, which provides

guidance in the diagnosis and treatment of radiation injuries, and the Centers for Disease Control website (http://www.bt.cdc.gov/radiation/clinicians.asp), related to radiation emergencies.

Common Pitfalls

- Failure to consider and identify radioactive contamination or irradiation injury.
- Failure to conduct disaster training, or performing such drills without addressing decontamination, use of PPE, and radiation surveys.
- Failure to manage concomitant injuries appropriately and to accomplish this prior to decontamination in critically ill patients.
- Failure to obtain an initial lymphocyte count for comparison to a follow-up 48-hour count.
- Failure to request appropriate consultation or to provide indicated chelation or antidote therapy.
- Failure to address psychological components of radiation exposure with patients and staff.

PART 2 • BITES AND ENVENOMATIONS

CHAPTER 367

Crotaline Snake Envenomation

Richard C. Dart and John B. Sullivan, Jr.

There are several thousand poisonous snakebites in the United States each year, resulting in several deaths (1). Most of these bites involve members of the *Crotalinae* genera: (1) *Crotalus* (rattlesnakes), (2) *Agkistrodon* (copperheads and water moccasins or cottonmouths), and (3) *Sistrurus* (pygmy rattler and massasauga). Although all states except Alaska, Hawaii, and Maine have poisonous snakes, most bites occur in the southeast, southwest, and western regions. The incidence is greatest between March and October, when snakes and victims are the most active.

The crotaline snakes have a temperature (prey)—sensing pit below and in front of the eye (the pupil of which is elliptical)—hence the common name “pit viper.” Venom is injected through a pair of maxillary fangs. Venom is mainly a mixture of digestive enzymes that cause local tissue necrosis and systemic vascular damage, hemolysis, fibrinolysis, and neuromuscular dysfunction resulting in pain and swelling that can migrate up an extremity over minutes to hours. Venom shock and pulmonary injury result from increased vascular permeability and coagulopathy, leading to edema and hemorrhage. Direct cardiac depressant effects may also contribute to shock (2). Venom composition varies with the species and also with the age of the rattlesnake. For example, young snakes tend to have more coagulopathic venom.

Up to 25% of bites do not result in envenomation (“dry bites”) (2). Most envenomations result in a combination of local and

systemic effects. However, some populations of Mojave rattlesnakes have venom (type A) that may cause presynaptic neuromuscular blockade with delayed respiratory failure and mild or absent local effects (3–5). Envenomations by *Agkistrodon* and *Sistrurus* sp tend to be less severe than those of *Crotalus* sp.

The size and species of snake, the location and depth of the bite, the victim's size and health, first-aid measures performed, the time to definitive therapy, and the type of therapy all influence the severity and outcome. The worst scenario is a small, victim deeply bitten by a large snake in the central body, neck, or face. Improper first-aid measures, delay in arriving at medical care, delayed diagnosis, and inadequate or unnecessary treatment adversely affect the outcome.

Bites by exotic snakes may occur in zoo and pet snake handlers and require specific antivenoms. A regional poison center (1-800-222-1222) or zoo can provide information on snake identification, expected toxicity, and antivenom location.

CLINICAL PRESENTATION

Dry bites produce no signs or symptoms other than those of a puncture wound. If envenomation has occurred, the victim (often an intoxicated male) typically notes sudden, severe pain at the bite site, soon followed by progressive swelling and, sometimes, paresthesias. Swelling is generally progressive.

Examination may show one, two, or more puncture wounds exuding bloody fluid. However, there are many reports of serious envenomation associated with scratches and single or multiple puncture wounds. Other local findings include erythema, ecchymosis, bullae, and, eventually, necrosis and ulceration. (Fig. 367.1) Bites about the face may lead to airway obstruction; those of the extremities may lead to compartment syndrome. Wound infection is a potential complication (6), although this is rarely seen clinically (7).

FIGURE 367.1 Blebs and ecchymosis from snakebite on the hand.

The most common clinical effects are pain and edema followed by coagulation defects. Systemic effects include nausea, vomiting, diarrhea, perioral paresthesias, salivation, lethargy, and weakness. Severe envenomations may lead to cardiovascular collapse, coma, seizures, dyspnea, respiratory depression, and gastrointestinal and pulmonary hemorrhage. Initial vital signs often show tachycardia and mild hypertension. Laboratory evaluation may reveal hemolysis, anemia, thrombocytopenia, coagulopathy (including severe fibrinolysis), and blood, protein, and glucose in the urine in severe cases. In severe cases, the chest radiograph may reveal pulmonary edema, and the electrocardiogram (ECG) may show dysrhythmias or ischemic changes.

DIFFERENTIAL DIAGNOSIS

Victims at the extremes of age, those with altered mental states, and those who are bitten while reaching into concealed areas may not realize they have been bitten. Snakebite may be misdiagnosed as a nonvenomous bite or sting or as puncture wounds and scratches from thorns and brush. A possible diagnosis of snake venom

poisoning can be excluded only by observation, documenting a lack of progressive local and systemic manifestations.

ED EVALUATION

On the patient's arrival in the emergency department (ED), vital signs and a rapid patient survey should be performed to determine the patient's clinical stability. The time and circumstances of the bite, the nature and severity of symptoms, any first-aid measures taken before arrival, and any history of allergies, medical problems, previous bites, and antivenom therapy should be noted. The bite site should be examined, noting the nature and extent of local findings. Progression of edema should be noted and can be marked (with the time recorded) on the extremity to help determine rapidity of spread (Fig. 367.2). Distal neurovascular status should be noted in extremity bites. Initially, the local evaluation should be repeated every 15 minutes. The general examination should focus on the cardiovascular, pulmonary, and neurologic systems.

FIGURE 367.2 Serial Measurement of swelling noted on a leg after a snakebite from a Western Diamondback.

The clinically relevant characteristics to describe when assessing severity are (a) local manifestations, (b) coagulation abnormalities, and (c) systemic effects. The change in these parameters over time is particularly important. An initially mild envenomation may progress to become moderate, severe, or even life-threatening over a period of minutes to hours. Coagulation abnormalities may peak as late as 3 days after envenomation.

KEY TESTING

- Mild bites: complete blood count; serum electrolytes, blood urea nitrogen, and creatinine levels; prothrombin time (PT or INR); platelet count; and urinalysis.
- Severe or progressive envenomation: above tests, plus creatine kinase, fibrinogen, and arterial blood gas analysis.
- A chest radiograph and an ECG are needed in patients with systemic signs or symptoms.
- Frequent reassessment of coagulation is critical.

ED MANAGEMENT

Advanced life-support measures should be instituted, as necessary. Prehospital personnel should establish intravenous (IV) access, give oxygen, and transport victims of venomous snakebites to a medical facility that possesses antivenom. Loose (lymphatic) tourniquets may be effective if used within 30 minutes of envenomation, but they are not substitutes for definitive care. If a tourniquet has been placed, it should not be removed until IV access has been established since hypotension may occur. The limb should be immobilized in a neutral position. Local wound care and tetanus prophylaxis should be provided.

Antivenom is the mainstay of crotaline snakebite treatment. Immunoglobulins in the antivenom neutralize venom proteins by forming antigen–antibody complexes. The primary indication for *Crotalidae* polyvalent immune Fab (ovine) (FabAV, CroFab) therapy is progressive worsening of local injury (e.g., pain, ecchymosis, or swelling), laboratory abnormalities (e.g., worsening platelet count,

prolonged coagulation times, decreased fibrinogen), or systemic manifestations (e.g., unstable vital signs or abnormal mental status) (8). If, after several hours, pain and edema remain localized to the bite site and coagulopathy does not develop, antivenom is unnecessary. Frequent reassessment for worsening of local, systemic, and laboratory manifestations cannot be overemphasized. The extent of swelling at presentation should be outlined with a marking pen, and the limb circumference should be measured at several sites above and below the bite. If any of these parameters worsen, antivenom therapy is usually warranted (see Fig. 367.3).

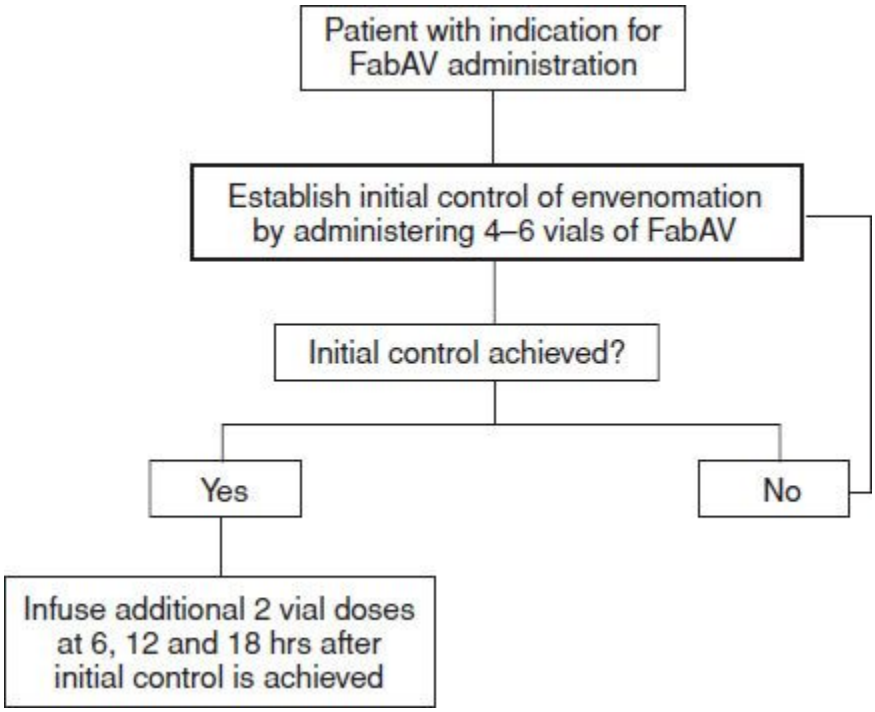

FIGURE 367.3 Algorithm for the use of crotaline snake antivenom.

The initial dose of FabAV for adults or children is four to six vials (Fig. 367.1). Six vials are used in patients with systemic effects or rapidly progressive local effects. Each vial of FabAV is reconstituted with 10 mL of sterile water. The contents of all vials are injected into a 250-mL bag of sterile water or saline. A smaller volume (but the same number of vials) is used in children or patients in whom large volumes could be detrimental. The initial infusion rate should be slow (e.g., 10 to 25 mL/hr) and then increased every few

minutes, until a rate is reached that will allow for infusion of the entire dose over 1 hour (e.g., 250 mL/hr). Continuous respiratory and cardiovascular monitoring should be performed. Antivenom should be given only in a critical care setting with epinephrine and antihistamines readily available to treat anaphylaxis, should it occur. The incidence of immediate hypersensitivity is 8%, and serum sickness occurs in 13% (9). Skin testing is not indicated prior to use of FabAV, as with some other antivenom products.

At the end of the initial infusion, the patient's condition should be reassessed. If local progression has not ceased and improvement in systemic and coagulopathic effects has not occurred, or if the patient continues to worsen, the initial dose of antivenom should be repeated. This process is repeated until initial control has been achieved. With severe envenomation, a large number of vials may be required for control. After initial control has been established, three maintenance doses of FabAV should be given: two vials administered every 6 hours for a total of six vials in an effort to maintain a clinically effective F(ab) plasma level. In clinical trials, patients receiving scheduled maintenance doses of CroFab have a lower incidence of local recurrence than those with repeat doses "as needed" (8).

Recurrence is defined as the return of any venom effect after the abnormality had initially resolved. Recurrences occur to some degree with most antivenoms (10). Local recurrence involves return of progressive local swelling after initial control is achieved. Coagulopathy recurrence involves the return of thrombocytopenia, prolonged PT or international normalized ratio (INR), or elevated fibrin split products. Local recurrences are uncommon. They usually occur within 12 to 24 hours of treatment. They should be distinguished from redistribution of blood/edema, secondary infection, venous thrombosis, and other causes of extremity swelling. Typically, local recurrence is managed with another two to four vials of FabAV, followed by regular maintenance infusions.

The recurrence of coagulopathy is more common, developing within 2 to 3 days and usually presenting after hospital discharge. Recurrent coagulopathy is often only partially responsive to further

antivenom administration. If given early, further FabAV may be effective in correcting the abnormality, but the beneficial effect may be weak and is often transient. Whether additional antivenom should be administered in such circumstances is controversial. Although coagulation tests are often abnormal, the risk of clinically significant hemorrhage is very low. Consequently, current recommendations suggest that recurrent coagulopathy be treated only if it is extreme and involves more than one coagulation abnormality or if there is evidence of significant bleeding (11,12). Most coagulopathy recurrences can be safely managed expectantly with close serial laboratory monitoring and bleeding precautions.

Concomitant supportive care (e.g., fluids and pressors for hypotension, blood component replacement for severe hematologic abnormalities, and respiratory support) is extremely important but often neglected (13). Blood products should be used only if the patient is actively bleeding or cannot receive antivenom (14). Serum sickness may range from a mild viral-like illness to severe urticarial rash, arthralgias, and other complications. In contrast to the immunoglobulin antivenom used in the past, FabAV usually does not cause serum sickness (10,15). Most cases can be treated as outpatients, with anti-inflammatory analgesics, antihistamines, and corticosteroids.

The effectiveness of antivenom in the treatment of snake venom poisoning has been extensively documented. Surgical interventions such as excision of the bite site or fasciotomy are not recommended. Experimental evidence in animals shows no beneficial effect (16–18). Fasciotomy should only be considered for documented increased intracompartmental pressure that is unresponsive to limb elevation, mannitol (1 to 2 g/kg IV), and antivenom (four to six vials of FabAV), (18). Cultures and antibiotic therapy should be initiated only if clinical signs of infection develop (7).

CRITICAL INTERVENTIONS

- Monitor patients closely for progressive local, systemic, and hematologic effects, which are indications for antivenom

therapy.
- Perform intensive care unit–level monitoring and have epinephrine and antihistamines (e.g., diphenhydramine) available at the bedside when giving antivenom, as anaphylactic reactions may occur.

DISPOSITION

Patients with dry bites who do not develop systemic or local progressive venom effects during an 8- to 12-hour observation period may be discharged. Those with severe or life-threatening bites and those receiving antivenom should be admitted to an intensive care unit. Admission to a floor bed is appropriate for the observation of patients with mild or moderate envenomations. Mobilization of the affected extremity can begin when the progression of swelling has ceased. Discharge is appropriate when swelling is decreasing, any coagulopathy has reversed, and the patient is ambulatory. Outpatient follow-up may be necessary for several days to monitor for infection and manage serum sickness.

Common Pitfalls

- Failure to diagnose envenomation because of a lack of history or inadequate observation of patients with suspicious wounds of unclear cause.
- Failure to provide supportive care and adequate doses of antivenom to patients with severe envenomation.
- Unnecessary administration of antivenom.

CHAPTER 368 Elapid Snake Envenomation

Richard C. Dart and John B. Sullivan, Jr.

Coral snakes are the only native North American snakes belonging to the elapid family. These brightly colored snakes are known for the potency of their venom. Fortunately, these snakes are usually small, nocturnal, and retiring, so few bites actually occur.

Coral snakes in the United States include (1) the Eastern coral snake (*Micrurus fulvius fulvius*), (2) the Texas coral snake (*Micrurus fulvius tener*), and (3) the Arizona (*Sonoran*) coral snake (*Micruroides euryxanthus*). The Eastern coral snake is found in the deep southeast United States; the Texas and Arizona subspecies are found primarily in the states whose names they bear (1). All these snakes are brightly colored, with black, red, and yellow rings that encircle their bodies. The red and yellow rings touch in coral snakes but are separated by black rings in nonpoisonous snakes, hence the rhyme, "Red on yellow, kill a fellow; red on black, venom lack." Unfortunately, victims may confuse the rhyme, especially when intoxicated (e.g., "Red on yellow, good fellow"). Elapids lack the facial pits seen in pit vipers and have nearly round pupils.

Coral snakes are docile and usually bite only during handling. When biting, they hold on or chew, allowing them to envenomate. Their venom is discharged through grooves on two small, fixed anterior fangs. Their small size makes it difficult, but not impossible, to envenomate humans seriously. The Eastern and Texas subspecies are larger and have seriously envenomated many patients (1). The Eastern coral snake appears to cause more severe envenomation

than the Texas coral snake; the Sonoran coral snake has not caused severe envenomation (1,2).

CLINICAL PRESENTATION

Coral snake envenomation can be difficult to diagnose and easy to underestimate. The typical bite shows little local damage and few initial symptoms. Minor pain without swelling may be present. This may be followed by numbness and weakness of the affected part. Systemic symptoms, which may take hours to develop, include drowsiness, apprehension, weakness, fasciculation, tremors, difficulty swallowing, dyspnea, salivation, nausea, and vomiting (3). Death may occur from respiratory muscular paralysis (2).

Physical examination may show fang marks and associated scratches. It is often possible to express a drop of blood. However, the history is particularly important, because significant envenomation has occurred even without bite marks being apparent, despite close examination. In such cases, injecting lidocaine under the suspected area may show minute beads of serosanguineous fluid exuding from fang punctures. Signs of systemic toxicity may be delayed in onset and include weakness of extraocular muscles, miotic pupils, bulbar paralysis, ptosis, respiratory depression, and convulsions. A creatine kinase level may be elevated.

DIFFERENTIAL DIAGNOSIS

The diagnosis of coral snake envenomation is usually clear from the history, because the snake frequently hangs on to the victim and has bright, identifiable coloring. When the patient cannot clearly communicate, the rapid development of cranial nerve palsy and progressive paralysis distinguishes it from other motor neuron diseases. If other causes are suspected, myasthenia gravis, Guillain–Barré syndrome, botulism, heavy metal toxicity, and central nervous system depressant medications may be considered.

Envenomation by other members of the elapid family such as the Australian red-bellied black snake, Ingram's brown snake, death

adder, and cobra, krait, mamba, Taipan, and tiger species may cause similar neurotoxicity. Amateur herpetologists are the typical victims, but zookeepers and other professionals are occasionally bitten. Specific exotic antivenoms may be available. A poison center (1-800-222-1222) can be consulted for assistance in evaluation, locating antivenom and management.

ED EVALUATION

The time and circumstances of the bite, a description of the snake, first-aid treatment before arrival, allergies, previous bites and antivenom therapy, medical history prior to presentation, and the nature, onset, and progression of symptoms should be noted. Although positive identification of the offending snake is helpful, it should not delay treatment. The physical examination should focus on the neurologic status, particularly cranial motor nerve and respiratory muscle function. Routine testing and imaging are not needed but the patient should be assessed for hypoventilation using tidal volume and blood gas analysis, and for muscle injury by creatine kinase if necessary. Other studies (laboratory, chest radiograph, electrocardiogram) should be obtained if clinically indicated.

KEY TESTING

- Blood gas for ventilation assessment if necessary.
- Creatine kinase for muscle injury in symptomatic patients.

ED MANAGEMENT

All patients with a history of coral snake bite should be examined. In symptomatic patients, prehospital care should consist of intravenous line insertion, maintenance of airway, and timely transport to a health care facility capable of antivenom therapy. Immobilizing the bitten extremity with a splint and applying elastic pressure bandages to retard venom spread may be useful.

Wound cleansing and tetanus prophylaxis should be provided. Patients who have clearly been bitten or who have developed

symptoms or signs of envenomation should be given at least five vials of *M. fulvius* antivenom (equine) by IV infusion. It is best not to wait for signs of toxicity to develop because the antivenom may not reverse them or prevent further deterioration once they appear. If symptoms progress, the dose of antivenom should be repeated. Allergic reactions can occur, and the same precautions as described for crotaline antivenom administration should be taken when giving coral snake antivenom (see Chapter 367). Although *M. fulvius* antivenom is neither effective nor necessary in Sonoran coral snake envenomation, it should be administered, unless a positive identification of this species has been made. The elective intubation of patients with bulbar signs or symptoms may prevent aspiration pneumonia (3).

The prognosis is excellent. There is normally no tissue loss or permanent neurologic dysfunction. Even without antivenom treatment, recovery can be expected over days to weeks if appropriate supportive care is provided (3,4). Hence, patients with allergic reactions to horse serum or antivenom can be managed successfully without antivenom therapy.

CRITICAL INTERVENTIONS

- Admit and monitor all patients with possible coral snake envenomation and monitor for neurologic dysfunction and hypoventilation.
- Administer *M. fulvius* antivenom to patients with known coral snake bites, even before the onset of symptoms.

DISPOSITION

All patients in whom the diagnosis of coral snake envenomation is entertained should be admitted to an intensive care area for at least 12 hours of close monitoring of vital signs and neurologic function. This disposition applies to patients with a definite bite, either by history or examination, regardless of whether they are symptomatic. After 12 hours of observation, patients with no evidence of

envenomation may be discharged. Those with severe envenomation may require several days of hospitalization.

Common Pitfalls

- Failure to appreciate that the onset of symptoms after coral snake envenomation may be delayed in onset and slowly progressive.
- Using antivenom inappropriately in patients with documented Arizona (*Sonoran*) coral snake envenomation and in those with allergic reactions to horse serum or antivenom.
- Failure to take the precautions for allergic reactions when giving coral snake antivenom.
- Failure to monitor for worsening toxicity after antivenom administration and to provide concurrent supportive care, especially airway protection and ventilatory assistance.

CHAPTER 369

Hymenoptera Envenomation

Paul F. Kolecki

The order *Hymenoptera* ("membrane-winged") includes bees, wasps, hornets, yellow jackets, and ants. Honeybees and bumblebees belong to the family *Apidae,* although wasps, hornets, and yellow jackets belong to the family *Vespidae.* Ants belong to the family *Formicidae;* fire ants are the most medically important species in this family. Anaphylaxis to *Hymenoptera* species affects up to 0.5% of the US population and causes about 50 deaths annually (1).

Winged Hymenoptera species are found throughout the United States, although fire ants are localized mainly in the southern states. Yellow jackets live in nests in the ground and in walls, while hornets live in nests built in trees or under branches. Wasps often build nests under roofs, behind shutters, and in dryer vents. Domestic honeybees in the United States are generally passive and do not sting unless provoked. Africanized honeybees (also called "killer bees"), indigenous to Central and South America and the southwestern United States, attack animals and humans in large; aggressive swarms cause mass envenomation.

The venom of winged Hymenoptera insects consists mainly of proteins, enzymes, and vasoactive amines; there is strong cross-reactivity between the venom within families. The venom of Africanized honeybees is very similar to that of domestic honeybees. Winged Hymenoptera species inject their venom quickly, typically causing immediate reactions. The main constituents of fire ant venom are piperidine alkaloids, which differs from the other

Hymenoptera. Fire ants are named because of the burning pain inflicted by their unique venom, which they inject more slowly, taking seconds to minutes. Significant morbidity and even mortality may occur in allergic individuals after a single envenomation by any of the Hymenoptera species.

Reactions to Hymenoptera stings are classified by the time of onset and the severity of the clinical reaction. Classification by time is subdivided into immediate and delayed reactions. Immediate reactions occur within minutes to a few hours after an envenomation and are mediated by IgE and vasoactive compounds within the venom. Delayed reactions are much less common than immediate reactions and typically develop several days to a week after the sting. These reactions are not IgE mediated.

Classification of a Hymenoptera reaction by severity is subdivided into three groups: local, systemic (e.g., anaphylactic), and toxic. Local reactions are common, with swelling, erythema, and a burning sensation at the sting site. These reactions are benign, resolve within hours to a couple of days, and are not predictive of systemic reactions to subsequent stings (2). Large local reactions can occur, perhaps involving an entire extremity. Patients suffering a large local reaction are at minimal risk (approximately 5%) of systemic anaphylaxis from subsequent stings.

Systemic reactions to Hymenoptera stings are either generalized or develop at a site remote from the sting site. Systemic reactions that produce life-threatening signs and symptoms are IgE mediated and commonly known as anaphylaxis. Potential physiologic effects associated with an immediate and severe systemic reaction include bronchiolar constriction, vasodilation, myocardial depression, increased capillary permeability, and the production of mucous. Most anaphylactic fatalities are a result of laryngeal edema and bronchospasm. An envenomation in someone with no history of a previous systemic reaction results in an anaphylactic reaction $<1\%$ of the time. However, a negative history of prior systemic reaction does not rule out the possibility of a severe reaction in the future. The risk of anaphylaxis to a subsequent Hymenoptera sting for a patient who has previously suffered venom-induced anaphylaxis is

30% to 60%. Because of the very strong cross-reactivity between the venoms within each Hymenoptera family, individuals sensitized to one species may also react to a sting by another species. Envenomation victims with Hymenoptera venom allergy and high levels of total IgE predominantly develop mild and moderate systemic reactions and may be protected from developing severe systemic reactions (3).

Toxic reactions, also known as direct systemic reactions, typically follow a massive envenomation, as seen with Africanized honeybees and result in the absorption of larger amounts of venom. Depending on the size of the victim, 10 to 50 simultaneous stings may be serious or fatal. The dose that will be lethal to 50% of humans (LD50) for honeybee stings has been estimated to be between 500 and 1,200 stings. Toxic reactions may occur immediately or may be delayed, and fatalities are a result of multisystem organ failure (4).

CLINICAL PRESENTATION

Local reactions caused by Hymenoptera envenomations are characterized by pain, wheal and flare formation, warmth, and pruritus at the sting site. These types of reactions occur in nonallergic individuals. Reactions to stings by winged species typically begin immediately and last for several hours. Fire ant stings often occur in clusters and develop into painful vesicles and sterile pustules during the first 24 hours and require up to 10 to 14 days for resolution. Large local reactions from fire ants typically are pruritic, erythematous, edematous, and indurated.

Local allergic reactions result in persistent swelling, pain, and erythema at the site of the sting. These reactions may progress to involve a large area (e.g., an entire extremity) during the first 2 to 3 days and may last for more than a week. Stings after accidental insect inhalation or ingestion by sensitive individuals may cause life-threatening swelling and obstruction of the pharynx, larynx, or esophagus.

Most anaphylactic reactions develop within minutes of envenomation and peak within an hour. Rarely, reactions may be

delayed as long as 6 hours after the envenomation. Recurrent reactions may occur for up to 2 days. Mild anaphylactic reactions are characterized by generalized flushing and urticaria, although moderate reactions are characterized by generalized weakness, chest or throat tightness, nausea, vomiting, diarrhea, and generalized angioedema. Cyanosis, dyspnea, stridor, hoarseness, confusion, coma, and collapse are seen in severe cases of anaphylaxis. Physical findings include hypotension, tachycardia, urticaria, wheezing, and laryngeal and pulmonary edema. Secondary complications associated with severe Hymenoptera-induced anaphylaxis include cerebral and myocardial infarction and coagulopathies (5,6). Systemic reactions also occur from fire ant stings and anaphylaxis occurs in 0.6% to 6% of envenomated fire ant victims.

Signs and symptoms of direct venom-induced systemic toxicity usually begin within minutes and include vomiting, diarrhea, generalized edema, collapse, loss of consciousness, confusion, headache, muscle spasms, and seizures. Vital signs typically reveal hypotension and tachycardia. Severe cases of direct systemic toxicity may be complicated by hemolysis, thrombocytopenia, disseminated intravascular coagulation (DIC), rhabdomyolysis, acute renal failure, hepatotoxicity, and encephalopathy. Systemic toxicity from mass envenomation may be delayed by many hours (4). A study of pediatric patients suffering mass Hymenoptera envenomations reported that vomiting does not portend involvement of other organ systems (7).

Serum sickness is an unusual delayed reaction that typically occurs within 1 week of envenomation Serum sickness is characterized by fever, arthralgia, myalgias, rash, and adenopathy and may include headache, glomerulonephritis, nephrotic syndrome, and necrotizing vasculitis. Delayed atypical hematologic and/or neurologic reactions may also occur following envenomations. These types of reactions include hemolytic anemia, thrombocytopenic purpura, Guillain–Barré syndrome, optic neuritis, other neuropathies, parkinsonism, and transverse myelitis (8).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for local reactions and anaphylaxis resembling Hymenoptera envenomations is extensive. Fortunately, the history of an encounter with a bee, yellow jacket, wasp, or fire ant is typically present.

Virtually any stinging or biting insect may produce limited local reactions of similar appearance. Extensive local reactions must be differentiated from an infectious cellulitis. Progressive extension of the initial reaction beginning shortly after the envenomation usually indicates an allergic component to the reaction. Inflammation, fever, leukocytosis, and lymphangitis beginning more than 24 hours after envenomation suggest a superimposed infection.

Anaphylactic reactions may be caused by a wide variety of drugs, foods, and environmental allergens. Anaphylaxis from Hymenoptera envenomation should be considered in any patient discovered outdoors during the spring and summer months with unexplained hypotension, urticaria, wheezing, and/or airway obstruction.

Patients who present with delayed reactions should be asked about recent insect stings, illnesses, and medication use within the previous several weeks.

Toxic reactions (e.g., direct systemic reactions or massive envenomation) can be differentiated from anaphylaxis in that systemic toxicity typically progresses more slowly, requires many stings, and causes multiorgan failure. Urticaria, pruritus, and wheezing are not part of a direct systemic reaction and suggest anaphylaxis.

Fire ant envenomations produce pustules within 24 hours. The differential diagnosis for pustule formation is also extensive, although the history of fire ant exposure is often evident. Risk factors for exposure include outdoor activities in endemic areas, especially when the affected areas are not covered by protective clothing.

ED EVALUATION

The history should include information pertaining to the time of stinging, estimated number of stings, previous Hymenoptera reactions, and past medical history. The time of onset, progression, and nature of symptoms should be noted. The physical examination should focus on the vital signs, airway patency, the cardiovascular system, and the skin. Lateral soft tissue neck radiographs and/or nasopharyngoscopy should be considered for patients experiencing stridor or voice changes without complete obstruction.

Patients with hypotension, loss of consciousness, or who suffer multiple envenomations (10 or more for children, 50 or more for adults) should have measurements of the complete blood count (CBC), serum creatine phosphokinase (CPK), liver function tests (LFTs), prothrombin time (PT), partial thromboplastin time (PTT), urinalysis (UA), and a metabolic panel to check for various manifestations of systemic toxicity (4). Measurements of the fibrinogen level and fibrinogen split products (FSP) should be considered with massive envenomation. Patients who experience hypotension, chest pain, or loss of consciousness should have an electrocardiogram (ECG) to rule out myocardial injury, ischemia, or infarction.

KEY TESTING

- Local reactions do not need any testing.
- Neck film or laryngoscopy is helpful for stridor or voice change.
- Systemic laboratories are important with hypotension and mass envenomation.

ED MANAGEMENT

The treatment of local reactions includes general wound care and symptomatic therapy for pain, swelling, and pruritus with analgesics, cool compresses or ice packs, elevation, and antihistamines. Envenomation sites should be cleaned, and tetanus prophylaxis should be updated, if necessary. Large local reactions can be treated with a short course of antihistamines, analgesics, and

steroids. Secondary infections are unusual; if present, they should be treated with appropriate antibiotics to cover skin flora.

With honeybee envenomation, the stingers often remain embedded in the victim's skin, and these should be removed. Previous recommendations were to remove stingers by scraping with the edge of a needle, scalpel, or credit card, rather than by pinching or use of tweezers, to avoid injecting any remaining contents from the attached venom sacs. However, in vivo experiments show that nearly all venom is injected within several seconds, and by the time a patient presents for emergency department (ED) care, stinger removal by pinching does not increase envenomation effects. Bee stinger removal by any method is acceptable.

The treatment for anaphylaxis as a result of Hymenoptera stings is very similar to that for anaphylaxis of other etiologies. Advanced life-support measures should be instituted as necessary. Prehospital personnel should give epinephrine at the first sign of an anaphylactic reaction. The dose and route of epinephrine depend on the severity of the symptoms and the victim's underlying medical problems; patients suffering from anaphylaxis should receive intramuscular or intravenous (IV) epinephrine (see Chapter 175).

Hypotensive patients should receive aggressive volume replacement with IV crystalloid. In addition, envenomated patients suffering anaphylaxis should receive an oral or IV antihistamine (e.g., diphenhydramine 0.5 to 1 mg/kg) and steroids (e.g., oral prednisone 0.5 to 1 mg/kg or methylprednisolone 1 to 4 mg/kg IV). A H_2-blocker (e.g., ranitidine) may also be helpful.

Severe anaphylactic reactions or marked local reactions that involve the nose, mouth, and/or throat require immediate airway control. Because most deaths are as a result of airway obstruction, early airway control by endotracheal intubation may be lifesaving in patients with respiratory distress from upper obstruction. A delay in airway control may result in further swelling, an unstable and difficult airway, and the potential need for a surgical airway. Patients who are wheezing or who have decreased lower-airway

movement should have inhaled α-1 adrenergic agonists (e.g., nebulized albuterol 2.5 mg). Continuous infusions of vasopressors (e.g., epinephrine, norepinephrine) may be necessary for recurrent or refractory hypotension. Higher-than-usual doses of α-adrenergic agents may be required when treating patients taking β-adrenergic blocking agents and those patients on chronic β-agonist medications.

The treatment of direct toxic reactions associated with multiple or massive envenomation is entirely supportive. These patients need to be monitored closely. These patients are potentially at risk for delayed organ dysfunction. Serial laboratory determinations of CBC, metabolic profile, LFTs, CPK, UA, fibrinogen, and FSP every 6 to 8 hours for 24 hours should be considered (4).

Delayed hypersensitivity reactions typically are treated with analgesics, antihistamines, and a tapering dose of corticosteroids.

Local fire ant reactions can be treated with cool compresses and cleansing with soap and water. Large local reactions may be treated with oral corticosteroids, antihistamines, and analgesics. Secondary infections should be treated with antibiotics. Anaphylactic reactions should be treated in the manner previously described.

CRITICAL INTERVENTIONS

- Administer epinephrine, corticosteroids, antihistamines, and IV fluids to patients with anaphylaxis who have abnormal vital signs, oxygen saturation, or dyspnea.
- Assess patients with dyspnea for upper airway obstruction, and perform endotracheal intubation in patients with severe or progressive signs and symptoms.

DISPOSITION

Patients who present immediately after envenomation should be observed for 1 to 2 hours for signs and symptoms of anaphylaxis. Asymptomatic patients may then be discharged. Milder anaphylactic reactions may be delayed, and patients should be instructed to return immediately if systemic symptoms ensue. In asymptomatic

patients with a history of previous anaphylactic reactions or severe local reactions, a prophylactic 3-day course of antihistamines and corticosteroids, beginning with a dose before discharge, should be considered.

Patients with mild to moderate anaphylaxis should be treated and observed for 4 to 6 hours or until asymptomatic. Patients suffering persistent or recurrent symptoms (excluding isolated urticaria), life-threatening reactions, persistent hypotension, or cardiac complications should be hospitalized with level of care determined by the severity of symptoms. All patients with anaphylactic reactions should be treated with a 3-day course of antihistamines and corticosteroids to prevent a relapse.

Patients with anaphylactic or severe local reactions should be given an epinephrine prescription (e.g., EpiPen or Ana-kit) and instructions for use. They should be cautioned about outdoor work and recreation, advised to wear shoes, long-sleeved shirts, and long pants, and to avoid wearing bright colors and perfumes. The use of insect repellents may be helpful. Referral to an allergist (directly or through the primary care physician) for possible desensitization immunotherapy should also be provided prior to discharge. Finally, the patient should be advised to obtain and wear a Hymenoptera allergy identification bracelet.

Patients suffering direct toxic reactions and multiple envenomations need careful observation for delayed end-organ damage and may need to be hospitalized depending on the number of stings and symptoms. Patients with local or delayed hypersensitivity reactions can be treated as outpatients with ED or primary care follow-up. Atypical reactions may require admission and referral to an allergist.

Common Pitfalls

- Failure to consider Hymenoptera-induced anaphylactic reaction in an unconscious or hypotensive patient found outdoors during the warm seasons.

- Failure to prescribe antihistamines and corticosteroids for 3 days after anaphylaxis.
- Failure to prescribe an emergency epinephrine kit for victims of severe local and anaphylactic reactions.
- Failure to refer patients with severe local and anaphylactic reactions to an allergist.

CHAPTER 370 Marine Envenomations

Alexandra E. DiTullio and Paul S. Auerbach

Encounters with venomous marine animals occur predominantly in warm tropical oceans. Because people may travel far from home for marine recreation, emergency physicians everywhere need to be familiar with the injuries and illnesses caused by aquatic life. This chapter reviews the most common invertebrate and vertebrate marine envenomations. We begin with descriptions of these unique animals and the mechanisms by which they cause injury and envenomation.

Members of the phylum Cnidaria exist either as sedentary polyps or as free-swimming, dome-shaped medusae and are divided into four main groups: (a) hydrozoans, which include fire coral, hydroids, and Portuguese man-of-war; (b) scyphozoans, considered to be "true" jellyfish (Fig. 370.1A); (c) anthozoans, including corals and anemones; and (d) cubozoans, such as "box" jellyfish (Fig. 370.1B). Considered to be the most dangerous are scyphozoans and cubozoans, in particular the box jellyfish *Chironex fleckeri* and the jellyfish *Carukia barnesi,* the latter known to cause the catecholaminergic Irukandji syndrome. Cnidarians possess venom-bearing stinging cells called *cnidocytes.* Each cnidocyte contains a stinging organelle known as a *nematocyst,* which carries a venom-laden coiled tubule released after stimulation of a "trigger." Nematocysts, predominantly located on the outer tentacles or near the mouth of the creature, are activated by physical contact and discharge with sufficient force to penetrate the dermis. The stinging process may trigger millions of nematocysts, as in the case of the Portuguese man-of-war. Cnidarian venom is a viscous mixture of

toxic and antigenic substances capable of stimulating hemolytic, proteolytic, cholinergic, histaminergic, serotonergic, and adrenergic activities. The venom can be neurotoxic, cardiotoxic, and/or dermatonecrotic (1).

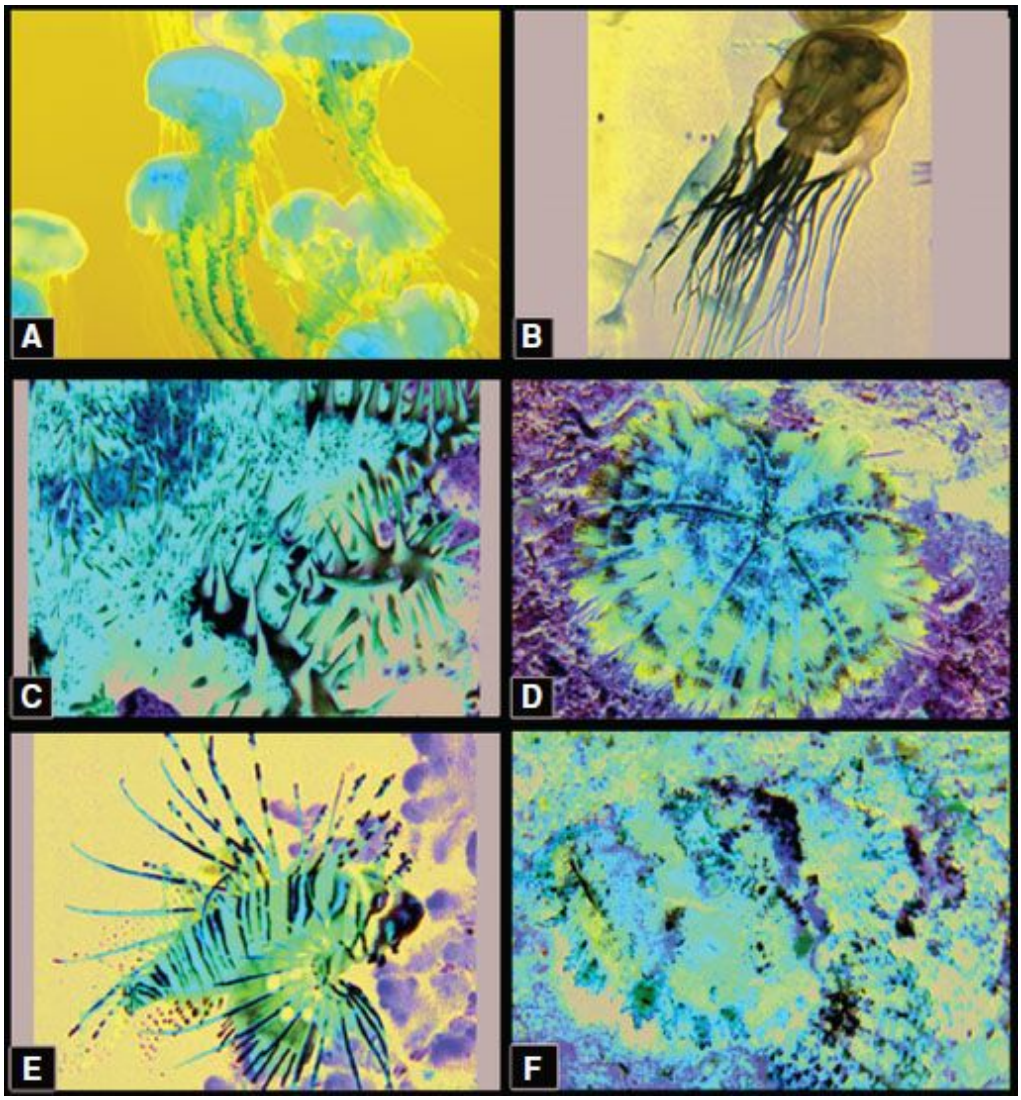

FIGURE 370.1 **A:** Jellyfish, "Pacific sea nettle." (Photo by Alexandra DiTullio) **B:** Box jellyfish. (Photo by Alexandra DiTullio) **C:** Crown-of-thorns starfish. (Photo by Paul Auerbach) **D:** "Fire" sea urchin. (Photo by Paul Auerbach) **E:** Lionfish. (Photo by Paul Auerbach) **F:** Scorpionfish. (Photo by Paul Auerbach)

Echinoderms include starfish, sea urchins, and sea cucumbers (1). Some starfish are covered with thorny spines of calcium carbonate

and produce a venom-containing slime. The potent crown-of-thorns species has ice pick–like spines that can puncture a diver's wetsuit. Crown-of-thorns starfish (Fig. 370.1C) venom has hemolytic, myotoxic, myonecrotic, and anticoagulant effects. Sea urchins (Fig. 370.1D) are protected by a hard shell and regularly arranged spines. Some venomous spines are sharp and brittle and break off easily; others may be blunt and nonvenomous. Sea urchin venom contains various toxic fractions, including steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances. If "seizing organs" (pedicellariae) become attached to a victim, they may be torn from the urchin's shell and continue to sting the victim for several hours (1). Sea cucumbers are wormlike bottom feeders that produce a liquid toxin called *holothurin,* which is concentrated in the tentacular organs that can be extended in defense. Some cucumbers ingest cnidocysts and secrete their venom as well (1).

Although most mollusk toxicity results from ingestion (1), cone snail stings and blue-ringed octopus bites are most hazardous to humans (2). Cone snails, found in Indo-Pacific seas, attack by injecting potent neurotoxins via a harpoon-like detachable tooth. Octopus bites are rare, but a bite from the tiny (<20 cm) Australian blue-ringed octopus releases venom similar to tetrodotoxin, which blocks peripheral nerve conduction (1). Most cases of envenomation are related to octopus handling.

Stingrays cause an estimated 2,000 injuries annually in US coastal waters (2). Injuries usually result when a human steps on the animal's dorsal surface, causing the barbed caudal appendage ("tail") to whip upward in a reflexive defensive response. The venom mechanism consists of a serrated spine or spines, venom glands, and enveloping integumentary sheaths. As the spine penetrates the victim the sheath ruptures, releasing venom and organic debris. Most injuries occur on the lower extremities. However, there have been cases of cardiac penetration. Stingray venom consists partially of heat-labile toxic components. Some stingrays generate electrical energy that can stun their victims (3).

Venomous fish from the family Scorpaenidae, found in the Indian and Pacific Oceans, are prized by aquarium enthusiasts. There are

three groups based on venom organ structure: The mildly venomous lionfish (Fig. 370.1E); the moderately toxic scorpionfish (Fig. 370.1F); and the deadly stonefish (3). Spines located on the dorsal, pelvic, and anal surfaces of these fish are covered with an integumentary sheath, under which venom travels along grooves from paired glands at the base. Envenomation occurs when a spine punctures the skin, causing the sheath to tear and expose the venom. Stonefish venom is commonly compared to that of the cobra snake and may retain full potency for 24 to 48 hours after death of the fish. The principal component (stonustoxin) is a nondialyzable, antigenic, and heat-labile protein. The toxin causes paralysis of cardiac, skeletal, and smooth muscles (3).

Catfish, both seawater and freshwater species, are endowed with venomous spines. Few are known to be aggressive toward humans, but some, including the oriental catfish, can inflict extremely painful stings. The tiny freshwater South American catfish *Vandellia,* also known as the "urethra fish," is more feared by native Amazonians than the piranha. At 2.5 to 7.5 cm in length, this fish sports short spines on its gill covers and has fins that can be locked in place when the fish becomes excited. *Vandellia* has been observed to implant itself in urogenital apertures, causing extreme pain and inflammation. It is unknown what attracts this fish to the human urethra, but swimmers should take precautions to avoid genital exposure (3).

CLINICAL PRESENTATION

Cnidarian envenomation may cause any or all three types of reactions- an immediate allergic reaction, immediate toxic (painful) reaction, and delayed allergic/immune response (1). Severity of envenomation is contingent on the species, the number of nematocysts discharged, and the sensitivity, size, and underlying health of the victim (1). In most envenomations, burning or stinging pain occurs immediately and can be very severe. Blister formation and pruritus lead to linear, urticarial, and painful eruptions that can take up to 10 days to resolve. The most common result of envenomation is localized dermatitis at the point of contact, which,

if left untreated, will often resolve in 1 to 2 weeks with occasional residual skin irritation and/or hyperpigmentation lasting up to 2 months. Further progression can lead to vesicular, ulcerative, hemolytic, or necrotizing lesions and possibly erythema nodosum or even gangrene (4).

Stings from the jellyfish *Physalia physalis* and *Stomolophus meleagris* have been reported to induce repeat eruptions for up to 2 to 3 weeks after the primary insult without repeated exposure to the animal (4). Sea bather's eruption, commonly misnomered "sea lice," is a dermatitis caused by larvae of the thimble jellyfish *Linuche unguiculata* (1). The eruption can occur within minutes or up to 12 hours after contact with ocean water and predominately affects covered areas of the body where the larvae are trapped, particularly underneath bathing suits. The reaction is intensely pruritic, with erythematous wheals, papules, or vesicles that persist for up to 2 weeks and may recur if the same bathing suit is worn again (4). Some victims develop gastroenteric symptoms after being stung.

In more severe envenomations, there are the local symptoms described above plus systemic involvement. Systemic signs and symptoms may appear immediately or be delayed by several hours. These include malaise, weakness, ataxia, dizziness, local cramping, muscle spasms, paresthesias, low-grade fever, nausea, vomiting, conjunctivitis, corneal ulcerations, anxiety, tachycardia, and hypotension. Fatal envenomations are due to arrhythmias, heart failure, respiratory arrest, and anaphylaxis (5). The Pacific box jellyfish *C. fleckeri* contains one of the most potent marine venoms, and fatalities from its sting have occurred within a few minutes of envenomation (6). Severity of envenomation appears to correlate with increasing size of the bell and length of tentacles. Some victims are able to struggle only for a minute before collapse (1).

The Irukandji *C. barnesi* causes symptoms similar to those seen with pheochromocytoma. Within 40 minutes of envenomation, the victim develops back, chest, and abdominal pain, nausea, vomiting, diaphoresis, agitation, hypertension, and tachycardia. The symptoms are due to massive catecholamine release. Victims may develop

pulmonary edema and myocardial injury 6 to 18 hours after the sting (5).

Sea anemones contain biologically active substances, such as neurotoxins, cardiotoxins, and hemolysins. The sting is compared in severity to that of a bee, characterized by a halo of erythema and petechial hemorrhage. The dermatitis may cause skin vesiculation and necrosis. The toxins of the sea anemone *Actinia equina* may cause coronary vasospasm leading to cardiorespiratory arrest, and those of *Condylactis* may cause hepatic failure (1).

Envenomations by the spines of starfish, sea urchins, and sea cucumbers cause immediate intense pain, which evolves into local muscle spasm, dermal erythema, and localized edema. The puncture sites often bleed profusely. Sea urchin spines frequently break off and may lodge deeply. Some contain purple or black dye that causes subcutaneous staining, giving a false impression of retained spines (4). Embedded spines in or adjacent to a joint or peripheral nerve may cause synovitis or neuropathy. Infrequent systemic symptoms, usually seen only if multiple spines enter simultaneously, include nausea, vomiting, paresthesias, abdominal pain, syncope, hypotension, and respiratory distress (1). Delayed reaction can occur weeks after the injury, consisting of a granuloma surrounding a retained spine fragment or diffuse inflammation at the puncture site. Puncture-induced infections are common. Of note, holothurin from sea cucumbers has caused conjunctivitis and blindness (1).

Most cone snail stings occur on the fingers or hands when handling the animal. Mild stings produce burning pain, followed by localized ischemia, cyanosis, and numbness. Severe envenomations produce paresthesias at the wound site, which may become perioral and then generalized (4). Partial paralysis may progress to respiratory failure. Systemic effects include pruritus, dysphagia, aphonia, and diplopia, with cerebral edema, coma, cardiopulmonary arrest, and death within a few hours. Victims usually recover within 6 to 8 hours, although some symptoms may take 2 to 3 weeks to resolve completely (1).

Octopus bites usually occur as a result of handling the creature and consist of one or two small puncture wounds. The initial bite often

goes unnoticed. Within 10 minutes, a burning sensation spreads to involve the entire limb, with erythema, swelling, tenderness, warmth, and pruritus. Most often there is no local reaction or only a tiny blanched area (1). If the bite is from a blue-ringed octopus, within 15 minutes the victim may experience neurologic symptoms that include perioral and facial paresthesias, diplopia, aphonia, dysphasia, ataxia, weakness, nausea, vomiting, muscle paralysis, and respiratory failure leading to death. Rapid neuromuscular blockade of the phrenic nerve, leading to paralysis of the diaphragm, causes respiratory failure (2). Because the toxin does not directly affect the heart, cardiac arrest is attributed to anoxia (1).

A stingray tail barb may cause a puncture wound or jagged laceration that is contaminated with stingray soft tissue and often spine fragments. Although lower extremity wounds are most common, infrequent truncal injuries cause most fatalities (2). Envenomation causes immediate and intense pain, which peaks at 30 to 60 minutes and may last up to 48 hours. A severe wound initially appears cyanotic and rapidly becomes erythematous and hemorrhagic, with possible early necrosis of muscle and fat. Systemic symptoms include weakness, nausea, vomiting, diaphoresis, vertigo, syncope, seizures, fasciculations, paralysis, hypotension, and, rarely, dysrhythmias and death (3,7). The stingray's mouth generates considerable suction and utilizes grinding plates for feeding, which have caused large hematomas or severed fingers (3).

Scorpionfish and stonefish are well camouflaged, so a sting usually occurs on the hands or feet of the unwary diver or fisherman who grasps or steps on the animal. Fish handlers and aquarists are also at risk. The puncture wound is immediately painful, with radiation proximally up the extremity. Untreated, the pain typically peaks at 60 to 90 minutes and resolves in 8 to 12 hours (3,8). Pain from a stonefish envenomation may be excruciating and persist for days. Rare deaths occur within the first 6 to 8 hours. The wound is first ischemic and then becomes cyanotic, with surrounding erythema and edema. Vesicles often form, and tissue sloughing with cellulitis may occur within 48 hours (4). Systemic symptoms are similar to cnidarian envenomation and include pulmonary edema, pericarditis,

syncope, hallucinations, and atrioventricular block (3). Wound complications include infection, neuropathies, and cutaneous granulomas that may require months to heal (4).

Catfish stings cause instantaneous stinging, throbbing, or scalding pain centrally, with pain radiating into and up the affected limb. Pain normally subsides within 30 to 60 minutes but may last up to 48 hours. Common sequelae include muscle spasm, diaphoresis, and fasciculations. Bleeding is often more severe than expected. Death is extremely rare (3).

Sea snakes found in the warm Pacific and Indian Oceans possess venom with neurotoxic, hemolytic, and cardiotoxic fractions, but cause mostly neurotoxic syndromes. The bite itself is usually not painful and may even go unnoticed. It is estimated that less than 10% of sea snake bites actually inject venom, yet worldwide 3% result in fatalities. Symptoms include muscle pain, peripheral weakness, paralysis, and respiratory failure (3).

DIFFERENTIAL DIAGNOSIS

The main considerations in the differential diagnosis are allergic reactions, trauma, infections, retained foreign bodies, and envenomations by other marine animals. Remember that there can be associated delayed reactions or systemic symptoms. For instance, sponges may cause erythema multiforme or an anaphylactoid reaction that may develop days to weeks after a severe exposure (1). There are also case reports of mononeuritis multiplex and Guillain–Barré syndrome occurring after jellyfish stings, sea urchin punctures, and envenomation from other marine creatures (1).

ED EVALUATION

The history should include the identity or description of the suspected envenoming animal and the time of onset, quality, and progression of symptoms. The specific geographic location visited should be noted. The physical examination begins with the skin, looking for wounds, rashes, and signs of infection. Many wounds need to be explored and/or x-rayed for radiopaque foreign bodies. Magnetic resonance imaging (MRI) is a fairly reliable method to

identify a foreign body; ultrasound techniques or computed tomography (CT) may also be useful. If there is no clinical sign of infection, "prophylactic" wound cultures have not been shown to be useful (1). Patients with abnormal vital signs, systemic symptoms, or altered sensorium should have an electrocardiogram and routine laboratory evaluation, including urine hemoglobin.

KEY TESTING

- Wound exploration and imaging to evaluate for foreign bodies.
- Wound culture if there are signs of infection.
- Troponin if suspected cardiotoxic envenomation with abnormal vital signs.
- Urine hemoglobin and creatine kinase for evaluation of rhabdomyolysis.

ED MANAGEMENT

An algorithmic approach to managing marine envenomations is depicted in Figure 370.2. Supportive care should be initiated in all marine envenomations. These injuries can be extremely painful, so do not hesitate to liberally treat pain locally and systemically, using opiates if needed (2). Because both fresh water and salt water contain an abundance of microbes, wound care is paramount, including irrigation, debridement of devitalized tissues, and removal of foreign bodies. Infected wounds should be cultured for both aerobes and anaerobes. Bacteria of concern include *Aeromonas hydrophila, Bacteroides fragilis, Chromobacterium violaceum, Clostridium perfringens, Erysipelothrix rhusiopathiae, Escherichia coli, Mycobacterium marinum, Pseudomonas aeruginosa, Salmonella enteritidis, Staphylococcus aureus, Streptococcus* spp., and *Vibrio* spp (4). Immunocompromised patients, especially those with hepatic disease, should be empirically started on broad-spectrum prophylactic antibiotics covering *Vibrio* spp. Minor wounds can be adequately treated with oral ciprofloxacin, trimethoprim–sulfamethoxazole, doxycycline, or cefuroxime. Extensive lacerations, deep punctures, joint involvement, or grossly contaminated exposures require a

parenteral third-generation cephalosporin, aminoglycoside, or other agent that covers *Vibrio* spp. A second antibiotic may be necessary to cover more common organisms, such as *Staphylococcus* (1,4). Tetanus prophylaxis should be administered according to the patient's immunization status.

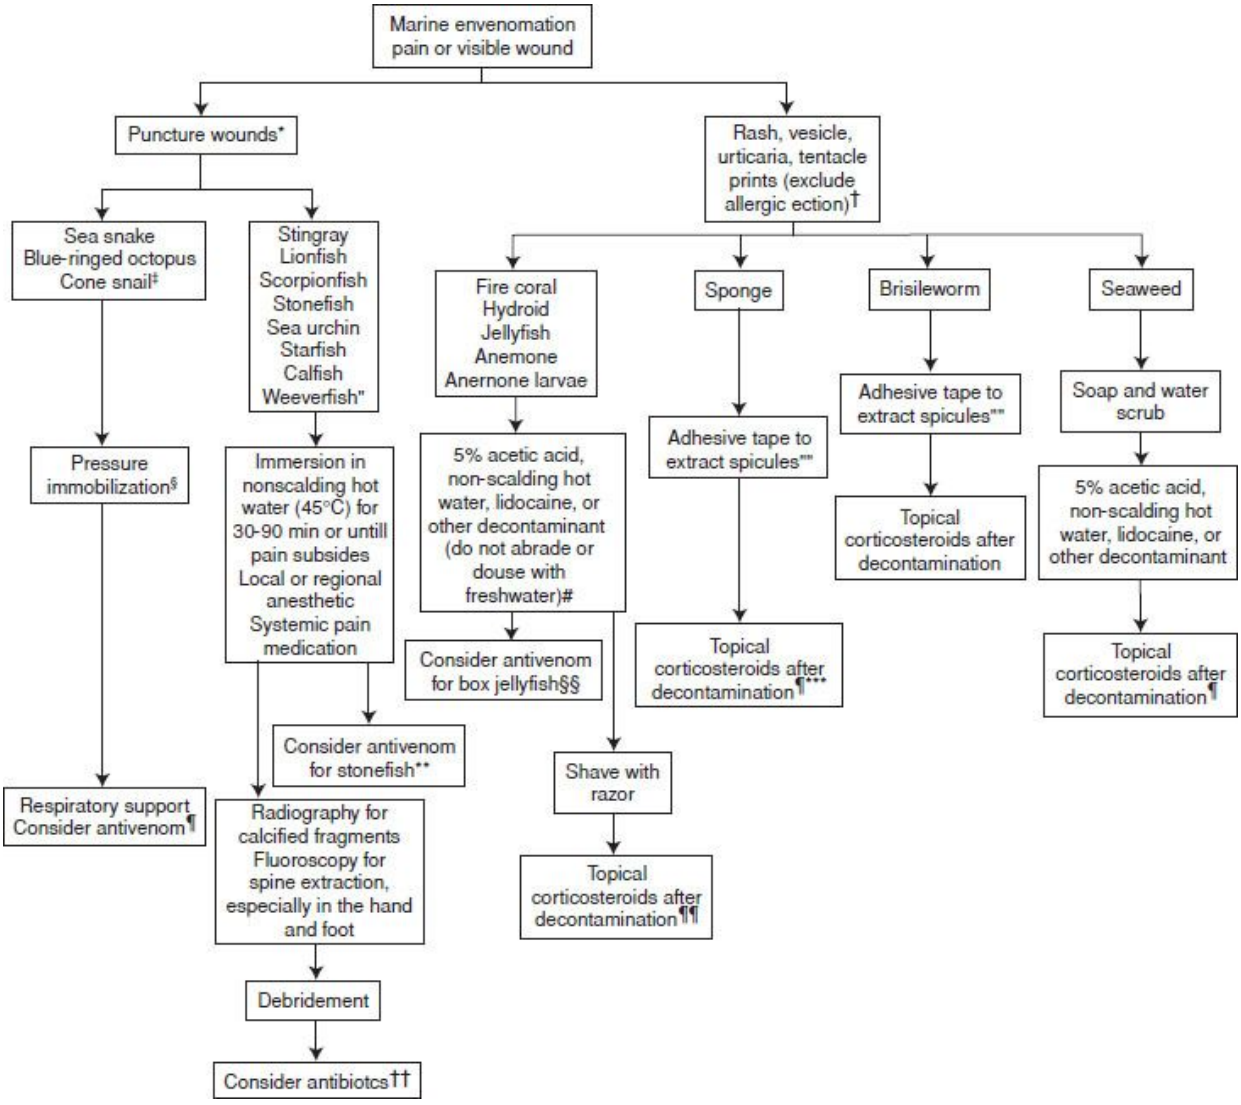

FIGURE 370.2 Algorithmic approach to marine envenomation. *A gaping laceration, particularly of the lower extremity, with cyanotic edges suggests a stingray wound. Multiple punctures in an erratic pattern with or without purple discoloration or retained fragments are typical of a sea urchin sting. One to eight (usually two) fang marks are usually present after a sea snake bite. A single ischemic puncture wound with an erythematous halo and rapid swelling

suggests scorpionfish envenomation. Blisters often accompany a lionfish sting. Painless punctures with paralysis suggest the bite of a blue-ringed octopus; the site of a cone shell sting is punctate, painful, and ischemic in appearance. †Wheal and flare reactions are nonspecific. Rapid onset (within 24 hours) of skin necrosis suggests an anemone sting. Broad “tentacle prints” with cross-hatching or a frosted appearance after application of aluminum-based salts suggests a box jellyfish (*C. fleckeri*) envenomation. Ocular or intraoral lesions may be caused by fragmented hydroids or cnidarian tentacles. An allergic reaction must be treated promptly. ‡Sea snake venom causes weakness, respiratory paralysis, myoglobinuria, myalgias, blurred vision, vomiting, and dysphagia. The blue-ringed octopus injects tetrodotoxin, which causes rapid neuromuscular paralysis. §As soon as possible, venom should be sequestered locally with a proximal venous-lymphatic occlusive band of constriction or (preferably) the pressure immobilization technique, in which a cloth pad is compressed directly over the wound by an elastic wrap that should encompass the entire extremity at a pressure of 70 mm Hg or less. Incision and suction are not recommended. ¶Early ventilatory support has the greatest influence on outcome. The minimal initial dose of sea snake antivenom is one to three vials; up to 10 vials may be required. ||The wounds range from large lacerations (stingrays) to minute punctures (stonefish). Persistent pain after immersion in hot water suggests a stonefish sting or a retained fragment of spine. The puncture site can be identified by forcefully injecting 1% to 2% lidocaine or another local anesthetic agent without epinephrine near the wound and observing the egress of fluid. Do not attempt to crush the spines of sea urchins if they are present in the wound. Spine dye from already extracted sea urchin spines will disappear (be absorbed) in 24 to 36 hours. **The initial dose of stonefish antivenom is one vial per two puncture wounds. ††The antibiotics chosen should cover *Staphylococcus, Streptococcus,* and microbes of marine origin, such as *Vibrio.* ‡‡Acetic acid 5% (vinegar) is a good all-purpose decontaminant and is mandated for the sting from a box jellyfish. Alternatives, depending on the geographic region and indigenous jellyfish species, include isopropyl alcohol, bicarbonate (baking

soda), lidocaine, papain, and preparations containing these agents. Application of water heated to 45°C may be effective for relieving pain. §§The initial dose of box jellyfish antivenom is one ampule IV or three ampules IM. ¶¶If inflammation is severe, steroids should be given systematically (beginning with at least 60 to 100 mg of prednisone or its equivalent), and the dose should be tapered over a period of 10 to 14 days. || ||An alternative is to apply and remove commercial facial peel materials. ***An alternative is to apply and remove commercial facial peel materials followed by topical soaks of 30 mL of 5% acetic acid (vinegar) diluted in 1 L of water for 15 to 30 minutes, several times a day, until the lesions begin to resolve. Anticipate surface desquamation in 3 to 6 weeks. (Adapted from Auerbach PS. Envenomation by aquatic invertebrates. In: Auerbach PS, ed. Wilderness Medicine. 6th ed. Amsterdam: Elsevier; 2012:1596–1628.)

Therapy for cnidarian envenomation includes field and/or emergency department application of a detoxicant, appropriate analgesia, and general supportive care. If a detoxicant is available (see later discussion), apply it immediately. Otherwise, rinse the wound with normal saline or hypertonic saline. Avoid applying fresh water (unless it is heated) or rubbing the affected area, because both actions are thought to cause discharge of nematocysts. Ice packs (preferably without external moisture) may alleviate pain, but application of nonscalding hot water (up to 45°C [113°F]) may be more useful (9). Remove any large tentacles with forceps or while wearing dishwashing-thickness gloves (1). If nitrile surgical gloves are worn, “double gloves” should be used if possible.

Topical therapy for jellyfish stings is guided by recommendations largely derived from empiric observations and the opinions of experts, and not from evidence-based randomized blinded clinical trials. Pouring vinegar (5% acetic acid) on the victim for 30 seconds inactivates the toxin of the box jellyfish *C. fleckeri.* A slurry of isopropyl alcohol and papain (meat tenderizer) has been effective against many other jellyfish species, presumably causing hydrolysis of proteinaceous toxins. It should remain on the skin for 15 minutes

or until the pain is relieved. Acetic acid may also cause relief of pain from Portuguese man-of-war stings, although this is still controversial in the literature (1). Other topical decontaminants that carry some favor for certain species include lidocaine, household ammonia (which may itself cause skin irritation), concentrated lemon or lime juice, or baking soda. Pain not resolved by nematocyst inhibition can be treated with lidocaine ointment or benzocaine spray to provide relief (9).

After the detoxicant has been applied, the adherent nematocysts need to be removed by applying shaving cream, baking soda, or talc to the affected area and shaving with a razor. Alternatively, a paste of sand and seawater can be prepared and the victim's skin scraped with a sharp-edged tool. It is possible that this shaving activity alone may be beneficial in relieving pain, even if this is not preceded by application of a topical decontaminant. If a sting is severe, the envenomed area should be immobilized, which might decrease venom distribution (1). However, the pressure-immobilization bandaging technique is no longer recommended (9).

Generally, only severe Portuguese man-of-war or box jellyfish stings result in rapid physiologic decompensation. Cardiopulmonary supportive care should be given as needed, and anaphylaxis should always be anticipated. Box jellyfish attacks have resulted in at least 67 deaths in Australia. Antivenom should be administered as soon as possible for any severe box jellyfish envenomation presenting with cardiopulmonary instability or extensive skin involvement (5). The initial dose is 20,000 units (one vial) over 5 minutes IV, or three vials IM, with standard hypersensitivity precautions. Additional treatment with magnesium sulfate may be of benefit, but remains controversial (2). Treat also for the renal sequelae of rhabdomyolysis. Although antibiotics are not always indicated, wounds should be closely followed for signs of infection. In addition, a topical antihistamine or mild corticosteroid may be soothing (4). A delayed reaction may recur after 1 to 2 months at the area of skin contact and should be treated with a 10- to 14-day taper of a glucocorticoid (1).

Along with the previously mentioned measures employed to treat cnidarian envenomations, patients presenting with the Irukandji syndrome, which is due to excessive catecholamine stimulation, may also need administration of IV phentolamine (5 mg initially, followed by 5 to 10 mg doses as needed) for control of hypertension (2). The use of IV $MgSO_4$ has recently been challenged (10). Beta-adrenergic blocking agents should not be used to control tremor, because these may precipitate hypotension or myocardial ischemia from unopposed alpha-adrenergic stimulation (1).

For starfish, sea urchin, and sea cucumber envenomation, the affected area should immediately be immersed in nonscalding hot water (up to 45°C [113°F]) as tolerated until the pain is relieved. Foreign bodies should be removed. Although some venomous spines may be absorbed within 24 hours to 3 weeks, it is best to remove those that are easily reached (1). External percussion to achieve spine fragmentation is contraindicated, and surgical exploration for embedded particles should be delayed until diagnosis can be made by soft tissue radiography, ultrasound, CT, or MRI. Spines within a joint or adjacent to a neurovascular structure should be referred to a surgeon for extraction of all fragments as soon as possible (1). For a possibly retained urchin spine, note whether the color change that was initially present has resolved over 48 hours. If this is the case, it is unlikely that a spine will be easily extracted from the surface, because it is unlikely that one is still present. Systemic analgesia is helpful, and prophylactic antibiotics should be given for deep puncture wounds (4). Systemic corticosteroids are for patients with diffuse delayed reaction with cyanotic induration, fusiform swelling in the digits, or focal phalangeal bony erosion. Sea cucumber envenomation management should include cnidarian detoxification and dermatitis treatment. If an eye is involved, it should be anesthetized and irrigated to remove residual foreign matter. The cornea should be examined with a slit lamp for defects. If there is no sign of infection, the inflammation should be treated with regular instillation of cycloplegic, mydriatic, and corticosteroid ophthalmic solutions. The patient should be referred to an ophthalmologist promptly for continuation of treatment (1).

No antivenom exists for treatment of cone snail or blue-ringed octopus envenomations, so management is limited to supportive measures. It is recommended, in addition to soaking the wound in nonscalding hot water, that the pressure-immobilization bandaging technique to contain the venom be used (2). Rapid respiratory failure can occur, so it is important to anticipate the need for oxygenation and mechanical ventilatory support. The clinical duration of blue-ringed octopus envenomation is 4 to 10 hours, after which a victim who has not suffered significant hypoxia usually begins to show improvement (1). Although some authors recommend wide excision to remove sequestered toxin and others favor irrigation, debridement, and wound observation, there is no compelling evidence that surgical therapy is routinely efficacious (1).

Treatment of stingray envenomation focuses on inactivating the toxin, alleviating pain, and preventing infection. The success of therapy is likely related to the rapidity with which it is initiated (3). The injury should be soaked in nonscalding hot water (up to 45°C [113°F]) for 30 to 90 minutes. If hot water is unavailable, the wound should be immediately irrigated with water or saline (7). Soaking the injury may not cause sufficient pain relief, so local or systemic analgesics may be necessary. Visible pieces of the spine or integumentary sheath will continue to envenom the victim and must be removed early. The wound tract needs to be explored, thoroughly debrided, and packed open for delayed primary closure. Prophylactic antibiotics are generally recommended owing to the high-risk nature of these injuries with respect to infections (3,7). Wounds to the abdomen or thorax must be fully evaluated by appropriate imaging studies. The patient should be observed for 3 to 4 hours for delayed onset of systemic symptoms before discharge (3). If the spine is lodged in the chest, abdomen, or neck, it should be managed as an impalement, with the spine immobilized in place until the victim is brought to a controlled operating room setting.

Management of scorpionfish or catfish envenomation is similar to that for stingray injuries. The wound should immediately be immersed in nonscalding hot water (up to 45°C [113°F]) for 30 to 90 minutes until symptoms subside. Recurrent pain that occurs after

several hours may respond to repeat hot water soaks. Appropriate treatment includes irrigation and thorough wound cleansing to ensure debris removal. Deep puncture wounds may need to be evaluated in the operating room (3). Stonefish antivenom is available for severe pain or systemic symptoms. One ampule should neutralize approximately two puncture wounds. As with any horse serum–based product, the possibility of a hypersensitivity reaction must be anticipated. Antivenom is rarely used for scorpionfish envenomation (3).

Treatment of sea snake envenomation includes the pressure-immobilization bandaging technique, early anticipation of respiratory failure, and administration of sea snake antivenom as soon as there is any evidence of envenomation. Victims who remain asymptomatic after 8 hours of observation can be safely discharged (3).

CRITICAL INTERVENTIONS

- Inactivate heat-labile toxins from stingrays, stonefish, scorpionfish, lionfish, catfish, and sea urchins by immersing the affected area in nonscalding hot water to tolerance.
- Administer specific antivenom for severe local tissue reaction and/or systemic toxicity as a result of box jellyfish or stonefish envenomation.
- Irrigate wounds, remove foreign bodies, and use appropriate antibiotic coverage to prevent infection.
- Provide appropriate supportive care, including pain and nausea control.

DISPOSITION

Some marine envenomations cause a delayed onset of symptoms, so a few hours of patient observation may be necessary. Victims with significant systemic signs and symptoms should be admitted to the hospital. A poison center can be consulted for treatment advice and to assist in locating antivenom. When discharged, patients need to be educated about wound infection, and follow-up care is essential.

Patients should be instructed to clean ulcerated wounds three times a day and have wounds first checked in 2 days.

Education on prevention of envenomations is important prior to discharge. Prevention of jellyfish stings is best accomplished by keeping exposed skin covered by a protective dive skin or wetsuit. Safe Sea is a topical sunscreen-jellyfish sting inhibitor that can be applied prior to entry into the water to prevent or diminish the severity of stings. To prevent stingray injuries, shuffling along the bottom when walking in the ocean is recommended. Ocean goers should be instructed to avoid handling marine life and always wear protective equipment.

Common Pitfalls

- Failure to appreciate that cnidarian envenomation pain can be reduced by topical lidocaine, vinegar, baking soda, isopropyl alcohol, or nonscalding hot water soaks and exacerbated by gentle freshwater irrigation.
- Failure to treat spine-induced envenomation pain with nonscalding hot water immersion.
- Failure to consider concomitant traumatic injuries and retained foreign bodies.
- Failure to consider appropriate antibiotic administration in certain circumstances for prophylaxis, and then for established marine bacterial infections.
- Failure to appreciate the severity of pain associated with marine envenomation.

CHAPTER 371 Scorpion Envenomation

Jeffrey R. Suchard

Several dozen scorpion species are found in the United States. Envenomation from almost all of these species causes only local pain and inflammation, which respond well to minimal supportive therapy. The Arizona bark scorpion, *Centruroides sculpturatus* (alternately *C. exilicauda* by an older taxonomy), is the only native species known to produce a potentially life-threatening envenomation. This scorpion is found throughout Arizona and in parts of some neighboring states and northern Mexico (1). Stings may occasionally occur elsewhere, as scorpions have been reported to stow away in a person's belongings (e.g., shoes, duffel bags) and be transported long distances before encountering their victims. Mild-to-moderate systemic effects have been reported in a minority of stings by the common striped scorpion, *Centruroides vittatus,* found in the Southwest and Texas and into southern Indiana and Illinois (2).

C. sculpturatus specimens generally measure about 5 cm (range, 1.3 to 7.6 cm) in length, have a thin tail and claws, and are a uniform tan, yellow, or light brown (Fig. 371.1). The last tail segment contains a venom apparatus and stinger. The bark scorpion prefers to reside in or near trees but may also hide in ground debris, camping equipment, clothing left unattended in natural desert areas, or even in areas long inhabited by humans. Scorpions are most active at night in warm weather, lying quietly while waiting to ambush prey. In defending themselves, they grasp the victim's flesh with pincers and repeatedly sting by thrusting their tails over their bodies.

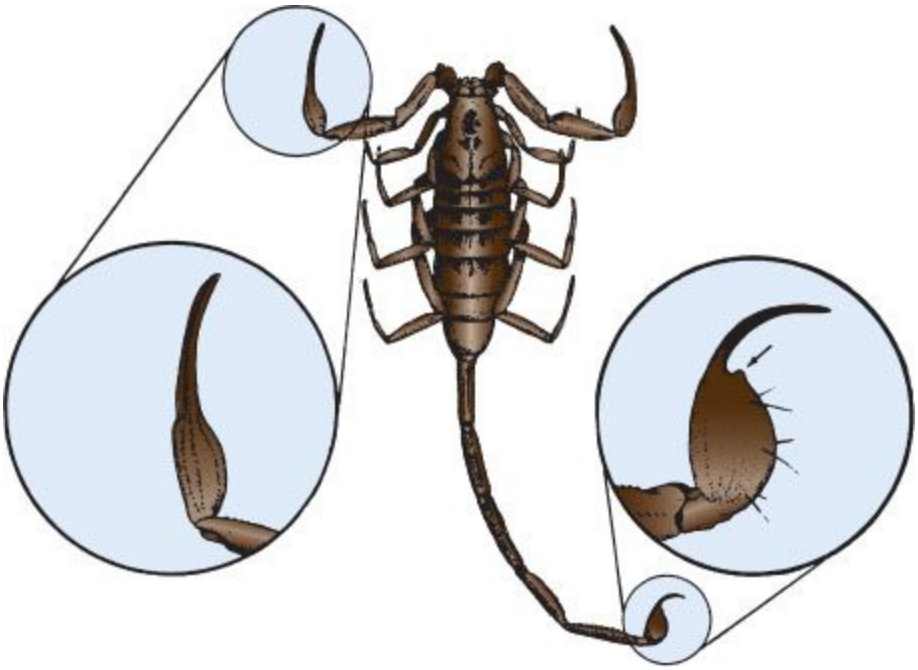

FIGURE 371.1 The sixth tail segment of *C. Sculpturatus* (bark scorpion) contains venom apparatus and stinger.

Although a sting from any scorpion can produce local pain, *C. sculpturatus* venom contains protein neurotoxins that cause repetitive firing of neurons by binding to sodium channels and preventing channel inactivation (1). Prolonged and excessive firing of parasympathetic, sympathetic, and somatic motor neurons produces various autonomic effects and uncoordinated, spontaneous activity in skeletal muscle. No destructive enzymes are present in the venom, so there is no inflammation or necrosis.

Scorpion stings are fairly common in endemic areas. Several thousand *C. sculpturatus* stings are reported annually to poison control centers in Arizona (3), although the majority of envenomations are not serious enough to require medical attention. Death from direct venom effects has not been reported in Arizona for several years; the lack of recent fatalities probably reflects advances in supportive medical care.

Severe envenomations by *C. sculpturatus* occur in 15% to 20% of children younger than age 10 who are stung and almost all severe envenomations occur in this age group. In contrast, 95% of

envenomations in those older than age 10 result in only mild-to-moderate effects. The life-threatening effects (myocarditis, pulmonary edema, shock) associated with dangerous scorpion species in other parts of the world have not been reported with species found in the United States.

CLINICAL PRESENTATION

C. sculpturatus envenomation results in the immediate onset of a painful tingling or burning sensation at the sting site. Tapping the sting site may produce severe pain, although no lesion is usually visible. Over minutes to several hours, pain and paresthesias may become generalized. Victims may complain of "thick tongue" and "trouble swallowing" yet lack objective abnormalities on examination. Young children frequently rub their noses, eyes, and ears and may present with unexplained crying.

Autonomic dysfunction is characterized by tachycardia, excessive secretions and, occasionally, vomiting and wheezing. Somatic motor abnormalities include roving eye movements, blurred vision, fasciculations (especially of the tongue), and poor control of pharyngeal muscles. Continuous jerking of extremities may be noted and misinterpreted as restlessness, seizures, or hysteria. The combination of uncoordinated pharyngeal musculature and muscles of respiration, increased secretions, and occasional wheezing may produce stridor, hypoxia, aspiration, and respiratory arrest in severe cases. Mild hyperthermia may also be noted, probably related to motor hyperactivity.

Envenomations can be graded on the basis of signs and symptoms (Table 371.1). In serious envenomations, abnormal motor activity may last 10 to 20 hours (1,4). Paresthesias may last up to 2 weeks.

TABLE 371.1
Scorpion Envenomations: Signs and Symptoms

Grade	Description
I	Local pain and/or paresthesias at site of envenomation
II	Pain and/or paresthesias remote from the site of sting
III	Either cranial nerve or somatic skeletal neuromuscular dysfunction:
	Cranial nerve dysfunction: Blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculations, stridor, slurred speech
	Somatic skeletal neuromuscular dysfunction: Jerking of extremity(ies), restlessness, severe involuntary shaking and jerking, which may be mistaken for seizures
IV	Both cranial nerve and somatic skeletal neuromuscular dysfunction

DIFFERENTIAL DIAGNOSIS

Bites and stings from other arthropods should be considered. The pain at the site of envenomation may appear similar to that seen after a black widow spider bite. However, patients severely ill from scorpion stings appear unable to lie still, whereas those bitten by black widow spiders can maintain a position for short periods before moving in an attempt to become comfortable. Black widow envenomations do not produce abnormal eye movements, fasciculations, and paresthesias. Tapping over the site of envenomation produces severe pain in the patient stung by a scorpion but not in someone bitten by a spider. Black widow spider bites frequently produce a characteristic halo lesion at the site of the bite; no lesion is usually visible after *C. sculpturatus* stings.

Tachycardia, excessive secretions, wheezing, and respiratory distress accompanying serious scorpion stings may be mistaken for asthma, airway obstruction from a foreign body, or poisoning with cholinergic agents such as organophosphate insecticides. Without a witnessed scorpion sting, other entities to be considered include central nervous system infections, seizures, and intoxication with sympathomimetics, phencyclidine, and nicotine. Methamphetamine toxicity is sometimes mistaken for *C. sculpturatus* envenomation in scorpion-endemic areas when young children present with unusual neurologic findings such as agitation or choreiform movements, occasionally leading to the inappropriate use of antivenom.

ED EVALUATION

If a sting was not witnessed, it should be determined whether there are scorpions near where the patient became ill. Physical examination should focus on vital signs, the airway, and neuromuscular function. No specific diagnostic tests are available. In patients with suspected aspiration, chest radiography is indicated, and arterial blood gas analysis should be considered. Rarely, severe envenomations can cause pancreatitis, rhabdomyolysis, and myocarditis, which would warrant obtaining baseline laboratory tests including serum amylase and/or lipase, creatine kinase, and an electrocardiogram.

KEY TESTING

- If signs of systemic illness: Pulse oximetry
- There is no confirmatory test available and patients without systemic illness require no specific testing

ED MANAGEMENT

Advanced life-support measures, with particular attention to airway management, should be instituted as necessary. Patients with grade I or II envenomations are treated symptomatically. Application of ice or oral analgesics is effective in most cases, but parenteral analgesia may sometimes be needed. As with any puncture wound, the patient's tetanus immunization status should be addressed.

Several therapeutic interventions have been used historically, although few have been rigorously tested and are not generally recommended. Except for very rare cases of anaphylaxis in patients previously sensitized to scorpion venom, there is no demonstrable benefit from steroids, epinephrine, or antihistamines. Respiratory distress associated with hypersalivation has been treated with atropine, sometimes obviating the need for aggressive airway interventions (5). The ideal dosing of atropine has not been determined nor is this practice considered a standard of care.

The marked motor hyperactivity seen in young children with high-grade envenomations has been treated with IV sedatives.

Barbiturate infusion was a former mainstay of therapy, although continuous midazolam infusions in the pediatric intensive care unit (ICU) have had good results. The median length of stay was just over 15 hours, and only 4 patients of 104 had transient hypoxemia (6). Sedation in a closely monitored setting has become the default therapy for high-grade scorpion envenomations since local production of a goat-derived *Centruroides* antivenom ceased in 2001 and the last vials expired in 2004 (3).

An equine-derived *Centruroides* (Scorpion) Immune $F(ab')_2$ antivenom product was approved by the US FDA in 2011 and is indicated for high-grade envenomations (7). It is available at a limited number of hospitals in the desert Southwest, primarily in Arizona, but also some in Nevada and Utah. Initial dosing is 3 vials IV diluted in normal saline to 50 mL and given over 10 minutes; additional 1 vial doses may be given as needed every 30 to 60 minutes (8). Patients need close monitoring with attention to airway control and the possibility of needing to treat severe allergic reactions. The great majority of patients (95%+) treated with this antivenom have resolution of systemic findings within 4 hours. Antivenom-treated patients should be advised that serum sickness may occur within a few weeks, which usually responds well to typical doses of steroids and antihistamines. The cost of scorpion antivenom therapy in the United States can be tremendous, with some reports of patients being charged tens of thousands of dollars.

CRITICAL INTERVENTIONS

- Airway control is of primary importance. Severely envenomated patients may require airway interventions as a result of hypersalivation and poor control of the oropharyngeal musculature.
- ICU admission for close observation is often necessary when complication such as aspiration pneumonia have occurred.
- Antivenom therapy can be effective in rapidly reversing toxicity in patients with severe systemic findings.

DISPOSITION

Patients with local pain and inflammation from a non-*Centruroides* scorpion sting should only require symptomatic treatment and can be discharged home.

Patients with grade I or II *Centruroides* envenomations should be observed for 3 to 4 hours after a sting for evidence of progression of symptoms. Those who do not manifest increased envenomation severity can be discharged to home with oral analgesics and follow-up with their personal physician as needed.

Antivenom therapy should be considered for patients with more severe *Centruroides* envenomations. If successful, these patients may be discharged home after ED observation with information about serum sickness and a treatment plan should it occur. In the absence of antivenom, children with grade III or IV envenomations should be admitted to an ICU. Adults without respiratory difficulties who require admission for pain control may be admitted to an unmonitored bed. Adults with more severe envenomations generally require intensive care.

Common Pitfalls

- Mistaking symptoms of severe envenomation for hysterical or uncooperative behavior or for seizures, especially in children.
- Relying on the absence of a visible lesion at the site of the sting to rule out scorpion envenomation.

CHAPTER 372

Black Widow Spider Envenomation

Dany K.M. Quan and Daniel E. Brooks

Originally used to describe *Latrodectus mactans,* black widow spider (BWS) is now used as the generic reference for up to 30 species of the genus *Latrodectus,* including *L. bishopi* (red-legged widow), *L. geometricus* (brown widow), *L. hesperus* (black widow), *L. indistinctus* (in Africa), *L. mactans hasselti* (redback spider), *L. Pallidus* (Asia), *L. paykulliana* (Europe), and *L. tredecimguttatus* (Mediterranean) (1). BWSs are found in the temperate regions of six continents and are widespread throughout North America, including the entire continental United States. There is evidence that their range is increasing. *L. mactans* and *L. hesperus,* most common in the western United States, are the classic black spider with a red, sometimes yellow, hourglass marking on the ventral abdomen. Several other species (including *L. variolus, L. bishop,* and *L. geometricus*) are found within the United States, varying in appearance depending on species, maturity, and region.

BWSs are commonly encountered in rural and suburban areas, typically in barns, garages, and woodpiles. Their irregularly shaped webs are usually spun in solitary environments, typically from the underside of low-level structures (e.g., a bench). The spiders can be found anywhere, however, and some species are arboreal. The female's larger size, up to 15 mm in body length with a 40-mm leg span, allows for a larger envenomation apparatus compared to the male, whose fangs and venom glands are often too small to penetrate human skin (2).

The active protein in *Latrodectus* venom (alpha-latrotoxin) is a potent neurotoxin, leading to the release of neurotransmitters (including acetylcholine and norepinephrine) at neuromuscular, central, and pancreatic synapses (3).

The *Latrodectus* spiders share a variety of venom components that are specific to different prey (i.e., vertebrates vs. crustaceans) (4,5). Furthermore, different envenomated species have significant differences in alpha-latrotoxin susceptibility and LD50, resulting in different clinical effects (1). Although research into the exact mechanism continues, it appears that alpha-latrotoxin utilizes several presynaptic membrane receptors and regulatory pathways to initiate exocytosis of secretory vesicles, with or without calcium involvement. In addition, the toxin forms membrane pores that disrupt neuronal membrane potential through ion exchange and compromised cell integrity (3,5).

Differences in venom structure and lethality depend on *Latrodectus* species, geographic location, and season, which may be important in human envenomations (5). A brown widow spider envenomation, for example, appears to be less toxic. BWSs may be able to control the amount of venom injected, another factor explaining the variance in clinical effects.

Latrodectism, defined as systemic effects from a BWS envenomation, affects thousands of patients each year and is the most important spider-related medical issue worldwide (1). Deaths worldwide from BWS bites are reported sporadically but previous estimated mortality rates of 10% are most likely overestimated due to selection bias or cases occurring prior to the development of antivenom. Each year, US poison control centers receive approximately 2,400 reports of suspected human BWS envenomations, but there has not been a reported fatality in the United States for over 25 years.

CLINICAL PRESENTATION

Envenomations typically occur from defensive bites and are more common in warmer, summer months. Males appear to be bitten

more often, and approximately 75% of bites occur on extremities (1,6). Reports of bites to the genitalia are historically related to the use of outdoor toilets but are now very rare.

The initial bite of a BWS is usually described as a sharp, transient pinprick or burning sensation but may go unrecognized. The bite site may reveal two small puncture wounds with minimal erythema or inflammation. A pathognomonic "target lesion" is commonly found, described as an erythematous ring, 2 to 6 cm in diameter, with a pale center at the bite site (7). This lesion usually develops within 2 hours of the envenomation and can last up to 24 hours, with varying degrees of tenderness. Other signs and symptoms typically begin within 30 to 120 minutes of the envenomation. A severe envenomation will progress from local to systemic symptoms that can include diffuse pain, muscle cramps (typically of the abdomen or back), tachycardia, and hypertension. Diaphoresis and piloerection can occur, sometimes isolated to the bite site (Table 372.1).

TABLE 372.1
Latrodectism

Pain
Muscle cramps
Abdominal rigidity
Headache
Restlessness
Diaphoresis
Nausea

Additional signs and symptoms include nausea, headache, fever, tremor, and weakness. Rarely reported signs are periorbital edema or ecchymosis, priapism, cardiac dysrhythmias (including reflex bradycardia), paralysis, myocardial ischemia, regional lymph node tenderness, and compartment syndrome. Herpes zoster and Horner syndrome have been reported after BWS envenomation, though causality has not been established. Young children may simply

present with inconsolable crying or restlessness. The onset of symptoms occurs about 1 hour after the bite (immediate to 12 hours) and, if untreated, wanes over several days. Symptoms peak within several hours but can be delayed for up to 24 hours. There are reports of symptoms lasting months.

In several case series of BWS envenomations the top three complaints most patients report are pain at the bite site (38% to 79%), abdominal pain (56% to 71%), and chest pain (17% to 30%). In a small case series of brown widow spider bites, pain at the bite site predominated at 93% of patients with systemic symptoms less likely (8).

The associated catecholamine surge can compromise patients at the extremes of age or those with significant underlying cardiopulmonary disease. Myocarditis with EKG changes, pulmonary edema, elevated troponins, and hypotension, has been reported (9). Pregnant patients may be at risk for uterine contraction, preeclampsia-like manifestations, and fetal complications (10). A series of 97 pregnant patients bitten by BWSs did not reveal any fetal loss (11).

DIFFERENTIAL DIAGNOSIS AND ED EVALUATION

BWS envenomation may be confused with any acute pain syndrome, such as acute coronary syndrome or an acute abdomen, where it can be confused with appendicitis and other surgical emergencies. Other, unwitnessed arthropod (hymenoptera, scorpion) or rattlesnake envenomations can mimic the associated signs or symptoms. Inconsolable crying in a child, particularly while playing or getting dressed (i.e., putting on shoes) outside, should raise the suspicion of an envenomation.

There is no diagnostic test to confirm a BWS envenomation, so a careful history, including activity just prior to the onset of symptoms, may aid in making the diagnosis. Leukocytosis and an elevated serum creatine kinase (CK), though nonspecific, are the most commonly reported laboratory abnormalities (1). Elevated CK, cramps, and diffuse myalgia may suggest rhabdomyolysis. Other

signs, such as fever (infection), roving eye movements with a tender bite site (scorpion sting), or gross hematuria (urolithiasis) suggest other acute clinical entities. Finally, a significant BWS envenomation may present with little, if any, objective clinical evidence, allowing patients with drug-seeking behavior to use this chief complaint when requesting narcotics or benzodiazepines.

KEY TESTING

There is no diagnostic test for the diagnosis or confirmation of BWS bites.

ED MANAGEMENT

After addressing the patient's airway and cardiovascular status, attention should focus on pain relief. Patients with mild-to-moderate discomfort should be offered oral opioid analgesics to manage the resolving pain over 24 to 48 hours. Those patients with significant pain should be treated with IV opioids, such as morphine or fentanyl, in titrated doses, and if necessary, a benzodiazepine, such as lorazepam, may be useful for agitation and anxiety. Effective amounts can vary tremendously; specific dosing should take into account the patient's weight, mental status, and comorbidities.

There are several equine-derived *Latrodectus* antivenoms, each targeted against the venom of one species. In the United States, the antivenom (Merck & Co., Inc.) is targeted against *L. mactans,* yet it is effective in treating envenomation from all North American species (12). This antivenom is available on a limited basis from the manufacturer but there is no indication whether it will continue to be manufactured. The presence of the common active venom component (alpha-latrotoxin) in all species allows for clinically useful cross-neutralization of venoms between different antivenoms, even those from different continents (13).

There are significant differences in experiences and recommendations for the use of antivenoms throughout the world (1,6,12,14,15). These differences are based on the *Latrodectus* species, patient presentation, antivenom, and physician training and

experience (especially for the use of *L. mactans* antivenom in the United States). The use of antivenom should be reserved for patients with severe pain or profound hypertension uncontrolled with opioids and benzodiazepines. A lower threshold for use is indicated for pregnant patients, particularly those with evidence of fetal distress, and patients with known cardiac disease and uncontrolled hypertension. The decision to treat with antivenom should be made as soon as possible, yet there are reports of (varying) effective antivenom use weeks to months after the reported envenomation.

A known allergy to the antivenom or horse serum (other equine-derived antivenoms) is a contraindication to its use. Relative contraindications include a history of severe allergic reactions, severe reactive airway disease (increased risk of anaphylaxis), and the use of a beta-blocker (may hinder the management of anaphylaxis). Decision making should take these risks into account. Anaphylaxis and death from the use of *L. mactans* antivenom are rare but reported (16,17).

An antivenom, commercially available in Mexico, called Antivenin Latrodectus (Black Widow) Equine Immune F(ab)2 (*Analatro*) is available as a clinical trial drug in the United States. This purified F(ab)2 is less immunogenic so the side effect profile is more favorable than the current FDA-approved antivenom and effectiveness of the antivenom is promising (18).

As with all antivenom administration, the patient should be in a closely monitored setting, have established IV access, and have a physician available at all times. Epinephrine, steroids, and antihistamines should be at the bedside in the rare case of an antivenom reaction. The manufacturer recommends routine skin testing; however, this procedure is neither sensitive for identifying patients at risk for allergic reaction nor safe from potential allergic reactions. A single vial of antivenom should be reconstituted in 50 to 100 mL of solution and administered IV over 30 minutes. Symptoms typically begin to resolve within 30 minutes, with complete relief within 2 hours. Rarely is the administration of a second vial required.

Patients with adequate analgesia but uncontrolled hypertension should be treated with an antihypertensive medication, preferably an infused short-acting agent that can be tapered as vital signs normalize. Beta-blockers, though used successfully, should not be used if antivenom administration is being considered, to minimize the theoretical risk of complicating an allergic reaction. Though once considered to be first-line agents, the use of IV calcium or "muscle-relaxants" is not supported by objective evidence and is no longer recommended.

Patients with severe, prolonged pain and myalgia may be at risk for rhabdomyolysis. Serum CK and urine output should be monitored.

Frequent reassessment is the key to rapid, effective pain control. Ultimately, the use of antivenom or the dosing of opioids and benzodiazepines are best determined by the patient's presentation, response to initial therapy, mental status, and vital signs. For those unfamiliar with spider bites, consulting a poison center (800-222-1222) may be helpful.

CRITICAL INTERVENTIONS

- Opioid analgesia for pain
- Benzodiazepines for anxiolysis
- Short-acting antihypertensive agents as necessary
- Antivenom with anaphylaxis precautions

DISPOSITION

Asymptomatic patients with a history or suspicion of BWS envenomation can be discharged to home after an observation period of at least 3 hours. Tetanus immunization should be offered, but prophylactic antibiotics are not indicated. Follow-up instructions should include monitoring for signs of infection.

Patients with mild symptoms typically respond well to oral analgesics, but one should consider the early use of parenteral medications for those with more significant pain. If the presenting pain and discomfort are rapidly relieved with initial IV medications,

a trial of oral medications is justified. However, the patient should be monitored for continued relief by oral analgesics prior to discharge.

Patients with severe symptoms requiring repeated administrations of parenteral analgesics or sedatives, or those with complicating medical conditions (i.e., cardiac disease, malignant hypertension, pregnancy) should be observed longer or admitted. Some patients may benefit from a patient-controlled analgesia pump.

Patients receiving antivenom can be discharged home after several hours of observation if they are asymptomatic and without evidence of anaphylaxis. They should be instructed about the signs and symptoms of serum sickness (malaise, myalgia, rash, and pruritus) and the need for follow-up if they occur. Serum sickness is treated with a tapering dose of oral steroids in most cases. The incidence of BWS antivenom-induced anaphylaxis and serum sickness is not known but appears to be low (2,6,14,18). Patients who receive antivenom should be counseled that they are at risk for anaphylaxis if reexposed to horse serum–containing medications.

Common Pitfalls

- Failing to consider the diagnosis, particularly in a patient with unexplained pain, muscle cramps, tachycardia, and hypertension.
- Using muscle relaxant or IV calcium for muscle spasms.
- Providing inadequate doses of analgesics and benzodiazepines for severe pain.
- Risking severe anaphylaxis with the inappropriate use of antivenom
- Failing to address other medical issues (such as fetal compromise, rhabdomyolysis, or hypertensive emergency) related to black widow envenomation.

CHAPTER 373

Brown Recluse Spider Envenomation

Dan Quan and Timothy Davie

Spiders of the genus *Loxosceles* are distributed throughout the world. *L. reclusa,* the brown recluse spider (BRS) and most important of these species in the United States, is most common in the southern Midwest states. Depending on the temperature, it prefers living outdoors (under rocks, woodpiles, and debris) or in structures (basements, attics, and storage areas). The name *reclusa* describes its behavior: It is nocturnal, avoids areas of activity, hides its web, and is seldom seen. The spiders are most often encountered from May to August (1). Bites may occur anywhere on the body, but are rare unless the spider is disturbed or threatened. Most victims are bitten while asleep, dressing, or working in the yard or house, and they may not initially be aware that envenomation has occurred.

L. reclusa is fawn to dark brown and has, on its dorsal cephalothorax, a violin- or fiddle-shaped, dark brown marking with the larger end toward the head. The body of a large spider will measure 1 cm in length by 0.5 cm in width. The short-haired abdomen is oval, and the legs are long and slender, measuring 1 to 5 cm. Three pairs of eyes, rather than four, is a distinctive but not unique feature of this genus. Although all Loxosceles species are often called *brown, violin,* or *fiddleback* spiders, the recognized common name *brown recluse* should be reserved only for *L. reclusa.*

Loxosceles venom contains at least 11 components, mostly enzymes with cytotoxic activity (e.g., protease, *S*-ribonucleotide phosphohydrolase, hyaluronidase, collagenase, esterase,

sphingomyelinase-D), which cause both local and systemic toxicity (2–4). Dermonecrosis is caused by endothelial cell damage by venom and ischemia secondary to thrombosis, inflammation caused by leukocyte infiltration, hemolysis, complement activation, and intravascular coagulation (5).

CLINICAL PRESENTATION

Most bites from the BRS have a benign clinical course. Cutaneous (necrotic arachnidism) and systemic toxicity (visceral loxoscelism) may occur, and the systemic reaction is not necessarily proportional to the local reaction. Systemic symptoms may develop before a necrotic lesion appears. Severity relates to the amount of venom injected, the bite location, and the victim's immune status. Children and debilitated victims are at greater risk for severe reaction, but the elderly are often asymptomatic, possibly because of immunity that developed from earlier bites in their lives. Children are more susceptible to severe systemic loxoscelism because of venom dose relative to body size. There is no clinical evidence that risk is greater during pregnancy.

Typically, the bite itself feels like a pinprick that, in a few hours, may itch, tingle, swell, become tender, red, or blanch and has a gravitational spreading. Frequently, a blister or purpuric lesion, or both, form. Necrosis with induration and eschar formation may occur within hours or as late as 2 weeks after the bite. The eschar then falls off, leaving an ulceration that may take months to heal. The most severe necrotic lesions occur in fatty areas such as the abdomen, thighs, and buttocks (6). Occasionally, an erythematous or violaceous reaction at the bite site, surrounded by a ring of pallor ("halo," "target," or "bull's eye" lesion), may be seen soon after envenomation. Vast edema may occur at the general bite site, especially on the neck and face. Angioedema of the airway may be life-threatening (7). The inflammatory reaction (pain, redness, induration, swelling, fever, lymphangitis, and leukocytosis) can be severe. A rarely seen immunodermatologic sequela of loxoscelism in adults is pyoderma gangrenosum with recurrent deep ulcerations.

Systemic effects develop within hours after the bite and include fever, chills, headache, malaise, weakness, nausea, vomiting, arthralgia, myalgia, and rash. These signs and symptoms progress for 48 to 72 hours and then resolve over another 24 to 48 hours. Laboratory findings may include anemia, thrombocytopenia, leukocytosis, hemolysis, and consumptive coagulopathy. Hemolysis may directly result in hemoglobinuria, renal failure, jaundice, and shock or indirectly cause congestive heart failure, coma, convulsions, and death (6). There are a variety of rash presentations. The more common scarlatiniform rash may appear within days and persist a few days. This pruritic scarlatiniform-like eruption represents a toxigenic erythroderma reaction to the venom rather than a *Streptococcus* or *Staphylococcus* infection. Because the spider does not transport bacteria, early infection is very unlikely. Cellulitis, bacteremia, or sepsis, is secondary to the victim's own flora (usually staph or strep). Envenomation may cause toxic hepatitis, pancreatitis, hematuria, and cardiac manifestations. Death, although rare, has occurred from multisystem organ failure, especially in young children (7).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes bites and stings from several other arthropods and many medical conditions (Table 373.1). "Spider bite" is overdiagnosed. It is controversial whether the other species of spiders in the United States cause necrosis, although there may be specific regional differences (6). Although there are other species of *Loxosceles* spiders in the United States, especially in the Southwest, their venom is less potent, so the dermal reaction and systemic effects are less severe. Erythema that evolves into a violaceous macule distinguishes a necrotic from a nonnecrotic bite. In addition, as the macule widens, the edge becomes irregular and the center sinks below skin level. In contrast, nonnecrotic lesions remain edematous, raised, and red (5). The diagnosis often becomes clear only in retrospect. There are only a few other natural toxins that cause hemolysis and possibly dermonecrosis (see Table 373.1)

(7). Unless an offending spider is positively identified, a more generic diagnosis such as "cutaneous necrosis," "necrotic arachnidism," or "necrotic arthropod bite or sting" should be used.

TABLE 373.1
Differential Diagnoses of Loxoscelism

Bites/stings from many marine, flying, and crawling creatures causing dermonecrosis
Suspected spiders in the United States: Argiope (orb weaver), Chiracanthium (running or sac spider), Loxosceles genera (fiddle or violin), Lycosa (wolf spider), Phidippus (jumping spider), Tegenaria agrestis (northwestern brown spider or hobo spider)
Dermatoses of many types
Stevens–Johnson syndrome, polyarteritis nodosa, sporotrichosis, lymphomatoid papulosis, purpura fulminans, erythema multiforme, toxic epidermal necrolysis, fixed drug and anticoagulant reactions, ecthyma gangrenosum, orf, herpetic whitlow, pyoderma gangrenosum
Medical conditions causing dermonecrosis
Emboli/thrombi, vasculitis/angiitis/periarteritis, frostbite, thermal injury, ischemic vascular ulcers, fat infarction, factitious ulcers (self-inflicted), foreign bodies, infectious hemorrhagic lesions (gonococcal, anthrax, zoster, pox), traumatic lesions, neoplasms, cryoglobulinemia
Other natural toxins causing hemolysis (and possibly dermonecrosis)
Coelenterata (Portuguese man-of-war jellyfish), hymenoptera (bees, wasps, fire ants, etc.), snakes (rattlesnakes, cobra, viper venoms), infections (Clostridium, Streptococcal/Staphylococcal)
Medical conditions causing hemolysis
Hereditary hemolytic anemias
Acquired hemolytic anemia
Autoimmune conditions caused by medications (methyldopa, penicillin, quinidine), underlying diseases, idiopathic
Nonimmune conditions caused by microangiopathic disorders, medications (nitrofurantoin, sulfonamides), chemicals (heavy metals), cardiac valve prostheses, physical agents (lightning, fresh-water drowning)

Source: Modified from Wasserman GS. Brown recluse and other necrotizing spiders. In: Ford MD, Delaney KA, Ling LJ, et al., eds. *Clinical Toxicology*. Philadelphia, PA: W.B. Saunders; 2001: 878–881.

ED EVALUATION

The history should include timing and circumstances of a lesion, description of the spider (seldom known), and progression of signs

and symptoms. The skin should be examined closely for typical lesions and a delayed rash in patients with acute hemolysis and/or coagulopathy of unknown etiology. The general examination should focus on vital signs, skin, musculoskeletal, and neurologic function.

All patients with suspicion of BRS envenomation should have a baseline complete blood count and urinalysis. Those with suspected hemolysis or significant systemic reactions should have plasma-free hemoglobin levels, coagulation studies including fibrinogen, and *d*-dimer measurement. Other helpful tests include liver function studies, renal function studies (electrolytes), lactase dehydrogenase (LDH), and serum amylase/lipase and rarely serum haptoglobin level/haptoglobin–binding capacity, biopsy, culture, or Gram stain. Inflammatory markers are almost always elevated. Hemolysis may be intravascular and/or extravascular. Extravascular hemolysis is not detected by finding hemoglobin in blood or urine and should be considered in any patient with a falling hemoglobin/hematocrit and elevated LDH or reticulocyte count. Several immunoassay tests have been developed to identify *Loxosceles* venom but are currently only research tools (6,8,9).

KEY TESTING

- Tests for hemolysis and coagulopathy include CBC, UA, plasma-free hemoglobin levels, fibrinogen, LDH, and blood type and cross
- Tests for supportive care as needed include liver and renal function, and amylase

ED MANAGEMENT

Treatment of necrotic arachnidism should be the same, regardless of the specific species of spider. A "benign neglect" approach nearly always results in an excellent dermal outcome. It is impossible to make an early prediction about which bite will result in a disfiguring lesion. General wound care usually suffices and includes tetanus prophylaxis, cleansing, and topical antibiotics. Corticosteroids injected locally or systemically and vasodilators

have not proven helpful in preventing or decreasing dermonecrosis (5). Routine antibiotics are not needed initially but may be indicated for secondary bacterial infection. Antipruritic or antianxiety drugs and cool compresses are often comforting (avoid heat, because it may stimulate a toxin-produced cascade of inflammatory reactants) (7). The bite site should be protected from further trauma, but immobilization is not necessary.

Analgesics can be given for pain, but drugs that affect platelet functioning are contraindicated because of possible bleeding problems. Early wide excision is ineffective, unnecessary, and expensive; produces complications, potentially allows venom to penetrate deeper into tissues and may cause disability or worsen scarring. Trimming rapidly enlarging bullae seems to stop their progression but does not necessarily reduce the risk of necrosis within the blister borders (7). Corrective surgery should be delayed for 4 to 8 weeks or longer, until necrosis is clearly demarcated (6). Necrotizing fasciitis or abscess warrants surgical intervention.

The treatment of systemic arachnidism consists mainly of aggressive symptomatic and supportive care. Corticosteroids (methylprednisolone, or equivalent, 1 to 2 mg/kg IV loading dose followed by 0.5 to 1 mg/kg IV every 6 hours) for 3 to 7 days ameliorate hemolysis, and a tapering dosage schedule can be used as necessary. Aggressive hydration can prevent acute renal tubular necrosis due to hemoglobinuria. Anemia and thrombocytopenia should be treated with component therapy (e.g., packed red cells, platelets), as needed. Complement in cryoprecipitate and fresh-frozen plasma reacts with venom components and contributes to further red blood cell destruction, so these products are not recommended (4,10). Blood type and screen/cross-match may be difficult because of interfering antibodies. In severe cases, newer coagulopathy therapies such as antithrombin III or recombinant factor VIIa may be useful.

Though early literature suggested that a polymorphonuclear leukocyte inhibitor such as dapsone may prevent ulceration if started early, there is no evidence supporting dapsone’s effectiveness in preventing dermonecrosis. Dapsone has potentially adverse

effects in patients with glucose-6-phosphate dehydrogenase deficiency hemolysis, methemoglobinemia, super infection, leukopenia, rash, toxic epidermal necrolysis and is especially dangerous for children.

Other treatments such as hyperbaric oxygen, colchicine, and triamcinolone have not been shown to be beneficial or effective. In animal studies, there is some evidence that tetracycline may be effective in the treatment of cutaneous loxoscelism by inhibiting matrix metalloproteinases (11). Although experimental antivenoms have been produced, they are not commercially available in the United States (12).

CRITICAL INTERVENTIONS

- Perform standard wound care for necrotic skin lesions.
- Perform serial clinical and laboratory assessments to rule out systemic toxicity.
- Treat hemolysis with high-dose parenteral corticosteroids, hydration, urine alkalinization, and packed red blood cell transfusion as needed.
- Avoid dapsone.

DISPOSITION

Patients who present immediately after a suspected spider bite should be followed as outpatients every 24 to 48 hours with at least a complete blood count and urine dipstick for 4 to 5 days after the bite. Patients who present with or develop large dermonecrosis or ulceration should be referred to a wound care surgeon for follow-up. Patients with significant systemic symptoms or hematologic abnormalities should be admitted for treatment and monitoring progression. Physicians unfamiliar with arachnidism should consult a regional poison control center or toxicologist for advice. Those hospitalized and having a benign course with stable physical and laboratory evaluations for 4 to 5 days can be discharged with follow-up in 2 to 3 days. Liberal admission for observation may be

prudent in very young or debilitated patients and in those judged to be unreliable regarding follow-up.

Common Pitfalls

- Diagnosing "BRS bite" rather than "necrotic arthropod bite/sting" or "necrotic skin lesion" when positive identification of the offending creature has not been made and alternative diagnoses have not been fully considered.
- Failure to appreciate that hemolysis secondary to *L. reclusa* envenomation may be rapid or insidious in onset and be intravascular and/or extravascular.
- Failure to perform laboratory evaluations on patients with signs and symptoms, especially skin lesions, highly suspicious for loxoscelism.
- Failure to discuss to warn patients about potential but unpredictable complications such as hemolysis, coagulopathies, secondary infections, and delayed wound healing and to arrange for follow-up.
- Overly aggressive early debridement of skin lesions.

ACKNOWLEDGMENT

The author thanks Gary S. Wasserman, MD for his contribution to previous editions of this chapter.

CHAPTER 374 Insect, Tick, and Mite Bites and Infestations

Michael James Burns

This chapter reviews the recognition and clinical management of bites and infestations associated with arthropods that are members of Class *Insecta* (*Hexapoda*) (insects) and Class *Arachnida,* subclass *Acari* (ticks and mites). Exposure to these arthropods may result in minor annoying local reactions, systemic allergic reactions, secondary bacterial infections, and the transmission of a host of serious systemic infectious diseases.

BIOLOGY, GENERAL DESCRIPTION, AND CLINICAL PRESENTATION

Arthropods are invertebrates having an exoskeleton, segmented bodies, jointed appendages, and bilateral symmetry (1). Insects have six legs and three distinct body regions—head, thorax, and abdomen —and include cockroaches, termites, lice, the true bugs (bedbugs, wheel bugs, assassin or kissing bugs), fleas, flies (which include mosquitoes), beetles, ants, wasps, bees, and others. Ticks and mites have eight legs as adults and nymphs, with one disk-shaped body region and no true head. Tick and mite larvae have six or fewer legs. Adult ticks are pea-size, whereas nymphal ticks and adult mites are about the size of a grain of sand or smaller. The arthropods most important to humans are hematophagous, meaning they must feed on warm-blooded vertebrates for blood or tissue fluid, with mouthparts that are designed for probing and sucking blood and

tissue fluids and saliva that contains substances that counteract host hemostasis.

Skin lesions from arthropod bites include wheals, papules, vesicles, and blisters which are produced by hypersensitivity reactions to salivary components or venom (1,2). Secondary bacterial infections can occur, and late cutaneous allergic responses may occur in atopic individuals and be confused with many infectious and noninfectious conditions.

BEDBUGS

Bedbugs (*Cimex lectularius*) are blood-sucking reddish-brown wingless insects about 5 mm long (adults), oval and flattened, smell like rotten raspberries, and can survive for long periods without feeding (1,3,4). The nymphal stages are smaller and also take blood meals. Except when venturing out to bite, they remain hidden on and in mattresses and in cracks and crevices of walls and floors near beds. Feeding is painless, occurs at night, and takes only 5 to 10 minutes, during which anticoagulants and vasodilators are injected. They often leave black specks on sheets and mattresses, a mix of feces, and heme. Common in tropical and underdeveloped countries, bedbug infestations have increased greatly in North America and Europe, not only in homeless shelters and places of overcrowding but in apartments, single-family homes, and upscale hotels. They are not known to transmit any disease. Bites may produce allergic reactions or no reaction at all. The typical presentation consists of extremely pruritic red papules or vesicles, sometimes painful, often in a linear or clustered pattern, most concentrated on skin that is exposed while sleeping. Anaphylaxis and urticarial and bullous lesions may occur. The rash is usually responsive to topical corticosteroids and oral antihistamines. Bedbugs are extremely difficult to eradicate. Resistance to insecticides is common. Excessive use of insecticides for treating bed bug infestations, usually pyrethroids and pyrethrins, their use contrary to label directions, failure to wash or change pesticide-treated bedding, and inadequate notification of pesticide application can cause human toxicity in the United States. The most

frequent manifestations of toxicity are headache, dizziness, respiratory tract irritation, dyspnea, nausea, and vomiting (5).

CONENOSE OR KISSING BUGS

Triatomine insects (Hemiptera, Reduviidae), commonly known as conenose, kissing, assassin, or reduviid bugs, are 1 to 3 cm long, brown or black, and good fliers (1,6). They are widely distributed in the western and southwestern United States, Mexico, and Central and South America. Usually found in the wild, they can adapt to live in cracks and holes of substandard dwellings and come out at night to feed on human blood. Their bites are usually painless, but allergic reactions to their bites can result in papular or nodular lesions and even anaphylaxis. They have been reported to be a common cause of anaphylaxis of unknown etiology in children living in endemic areas of the United States (7). Some species can produce intensely painful bites with marked swelling at the bite site. Several members of this group (*Triatoma, Rhodnius*) transmit the protozoan parasite *Trypanosoma cruzi* (causative agent of American trypanosomiasis or Chagas disease) to humans. These insects are plentiful in southern Arizona and southern California and a high proportion in these regions have been found to be infected with *T. cruzi* (8). Wheel bugs (*Arilus cristatus*) are true bugs that bite humans only in self-defense (1). They are 3 cm long and gray, have a small narrow head and a cogwheel-like crest on their thorax, and are found in the southern United States. The bite causes immediate intense pain with swelling and inflammation, but they do not transmit any diseases. Blister beetles are large plant-feeding insects, commonly found in the southeastern, central, and southwestern United States, whose body fluids produce large painless blisters within a few hours after contact with live or dead beetles (1). Mild tingling or burning can occur prior to onset of blistering. The blisters are usually not serious and resolve within several days. Ingestion of beetles or their products may cause vomiting, abdominal cramps, and diarrhea.

CATERPILLARS AND CENTIPEDES

Some caterpillars have urticating hairs or spines that secrete a toxin when exposed to human skin, causing a burning sensation, swelling, numbness, or intense stabbing pain (1). Other caterpillars may cause a self-limited, pruritic, papular dermatitis after the skin comes in contact with hairs of the caterpillars. Outbreaks of caterpillar dermatitis have been reported among children at childcare facilities, and are frequently misdiagnosed by physicians as varicella, scabies, flea bites, mosquito bites, contact dermatitis, viral exanthems, and methicillin-resistant *Staphylococcus aureus* MRSA infections (9). Because the hairs or spines can remain embedded in the skin, repeated application of adhesive tape at the site to remove the spines may be needed, in addition to cold compresses, topical corticosteroids, and oral antihistamines.

Centipedes (Class *Chilopoda*), which are not insects or arachnids, can cause a painful "bite," which can become red and swollen (1). The bite is produced and injected by sharp claws on their first pair of legs, which have attached venom glands. Treatment includes washing with soap and water, applying cool compresses, and oral analgesics, with anecdotal benefit after immersing the area in hot water.

FLEAS

Fleas feed exclusively on blood (1). The cat flea (*Ctenocephalides felis*), which also infests dogs and other mammals, is the predominant flea species in North America. Fleas, which are wingless and cannot fly, are easily recognized by their jumping behavior. Fleabites in humans cause allergic reactions and result in clusters or irregular groups of several to a dozen or more where the flea has explored and probed. In the allergic person, a pruritic wheal forms around each probe site within 5 to 30 minutes. Indurated papules and occasionally vesicular or bullous lesions develop within 12 to 24 hours, accompanied by intense itching, and may last a week or more. Fleas can transmit plague (*Yersinia pestis*), murine/endemic typhus (*Rickettsia typhi* and *Rickettsia felis*), and cat-scratch disease (*Bartonella henselae*). Children who ingest fleas containing the larval stage of the dog and cat tapeworm, *Dipylidium caninum,* may become

infected with the adult tapeworm. The small female chigoe flea, *Tunga penetrans,* burrows into the skin of persons living or traveling in tropical and subtropical areas of North and South America, the West Indies, and Africa, producing a disorder known as *tungiasis.* It grows to about 1 cm within 2 weeks and lays eggs beneath the dermis. It commonly infests the legs and feet, including the areas between the toes or under the toenails, and produces intense inflammation and itching. One sees a black dot in the center of a pustule. These are surgically removed by widening the cavity and removing the flea intact.

FLIES, GNATS, MOSQUITOES

Black flies are smaller than mosquitoes, travel in large swarms, and are vicious biters (1). Allergic reactions to the bites result in red itchy papules and nodules with surrounding swelling and occasionally systemic allergic reactions with fever, wheezing, and diffuse urticaria. Deer and horse flies are large flies whose bites produce deep, painful wounds that often become secondarily infected (1). Bite lesions are solitary or scattered, not grouped or linear. Local and systemic allergic reactions can occur. Stable fly bites produce small papular lesions. Biting midges, sometimes called "no-see-ums" or "biting gnats," are fierce biters and are so small that they can pass through ordinary screens. Their bites produce small papular lesions with red halos and wheals. Deer flies can transmit tularemia, but black, horse, and stable flies and biting midges do not transmit any diseases in North America.

Mosquito bites can result in allergic reactions, producing multiple, scattered lesions that are not linear or grouped (1). A wheal and flare may be seen 30 minutes after the bite, and delayed onset of pruritic papules is common. Mosquitoes are the most important arthropod vectors of disease in the world because of their transmission of malaria, filariasis, yellow fever, dengue, West Nile, and other encephalitis viruses (10,11).

MAGGOTS

Myiasis is an invasion or infestation by maggots, the larvae of two-winged flies (*Diptera*), and is most commonly found in debilitated or comatose persons, the homeless, alcoholics, those with peripheral vascular disease, or young children (1). It occurs when the female fly lays eggs near a wound or when the fly deposits freshly hatched larvae directly in a wound. The larvae of some fly species are able to penetrate skin and invade normal tissues, whereas others are capable of living only on the surface of the wound. Although usually occurring in wounds, myiasis can also occur in the nose, mouth, sinuses, eyes, anal region, vagina, and bladder. Myiasis is not contagious from person to person, as fly larvae are not capable of reproduction. Transmission occurs only via an adult female fly. Physical removal of each individual maggot, often surgically or by use of a large suction catheter, is the most effective treatment (1,12). If large numbers of maggots are found in a wound, soaking the area with vegetable oil followed by irrigation and then individual removal of remaining larvae may be effective. There are no medications or chemicals that will dislodge maggots. When exposed to a chemical insult, maggots retract into the wound, making it more difficult to remove them. Furuncular myiasis is produced by the larva of the human botfly (found in Mexico and Central and South America) and by the Tumbu fly (found in tropical Africa). The larvae burrow into host tissue, producing painful pruritic cutaneous nodules called *warbles,* each with a central opening or punctum. The person sometimes feels something moving. Visitors may acquire this disorder while traveling and return home before the maggot completes its development. These lesions are easily mistaken for staphylococcal boils. Furuncular myiasis is treated by surgical removal of the intact larvae or by applying petroleum jelly, suffocating the maggot, which may come wriggling out backward. “Bacon therapy” is also effective; the punctum is covered with raw meat, and in a few hours, the larvae migrate into the meat and are then easily extracted.

LICE AND MITES

Lice are tiny, elongate, soft-bodied, light-colored, wingless insects that feed on blood (1,13,14). Three species infest humans: (1) the human body louse (*Pediculus humanus corporis*), (2) the human head louse (*Pediculus humanus capitis*), and (3) the pubic or crab louse (*Phthirus pubis*). The body louse lives on clothing, lays its eggs (nits) on clothing, and leaves the clothing only to take a blood meal. It can transmit epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and louse-borne relapsing fever (*Borrelia recurrentis*). The head louse and pubic louse are not known to transmit any diseases. All lice are transmitted from person to person by close body contact, possibly by sharing of hats, combs, and brushes (head louse) or by sharing clothing (body louse). Humans infested with lice often develop itchy red papules with excoriated areas that can become secondarily infected. The adult lice are often difficult to see, but the nits of the head louse and pubic louse can be found attached on shafts of hair near the base. Head louse infestation is most common in white schoolgirls and affects all social and economic backgrounds. Pubic lice can sometimes be found in the eyebrows and eyelashes, in axillary hair, on the coarse trunk hairs of males and, rarely, in the scalp. Bluish-gray macules, known as *blue spots,* may sometimes be seen on the skin in pubic lice infestation. People infested with pubic lice often have other sexually transmitted diseases.

Mites look like tiny small hairy ticks, with one disk-shaped body segment and no true head. Many species bite humans that cause skin lesions from allergic reactions but the mites do not live on humans or their clothing (1). Chiggers is a condition caused by bites by the larvae of the chigger (or harvest) mite (Family *Trombiculidae*) (1). These mites are found in grasses and scrubs, especially at forest edges. Chigger mite larvae, which are tiny (0.2 mm long); round; and red, yellow, or orange in color, bite humans and inject saliva that dissolves host tissue, then feed on the dissolved tissue. Pruritic macules and wheals develop within 3 to 6 hours, followed by intensely pruritic papules and pustules at 10 to 16 hours. Lesions are often linear or grouped. Numerous other species of mites will bite humans, causing painful pruritic red papules. Persons bitten by

chicken mites and straw itch mites may have thousands of lesions. The tiny itch mite *Pyemotes herfsi* has recently caused outbreaks affecting thousands of people in Kansas, Nebraska, and Missouri; a person may have hundreds of bites resulting in a severe pruritic papular dermatitis. The house mouse mite transmits rickettsialpox (*Rickettsia akari*) to humans in the United States. Unlike the scabies mite, none of these mites live on humans.

SCABIES

Scabies, an infestation of the epidermis by *Sarcoptes scabiei* var. *hominis,* which spends its entire life on human skin, is transmitted by close body contact (15). The fertilized female mite, too small to see with the naked eye, burrows into the epidermis, and lays two to three eggs daily for 30 days (1). Larvae hatch in 3 to 4 days and migrate to the skin surface. Maturation from egg to adult takes about 10 to 14 days. The mites feed on cells of the stratum corneum. Their secretions and excretions sensitize the host and produce irritation and itching with pruritic crusted red papules, papulovesicles, pustules, and weeping eczematous lesions. Transmission is by direct skin-to-skin contact. Transmission by infested bedding, towels, or clothing is uncommon except in the case of crusted (hyperinfestation) scabies. The incubation period after infestation until symptoms appear is about 3 to 6 weeks for a first infestation but may be much shorter (as little as 48 hours) in recurrent infestations. A person may be very contagious before any symptoms or lesions even occur. There are 5 to 20 mites on the body in a typical infestation, usually found in burrows on the hands, wrists, elbows, knees, beltline, penis, the breasts of females, and the feet of children, but they are especially common in the webs of the fingers and the folds of the wrists. In infants, lesions are frequently found on the scalp, face, palms, and soles. Burrows are often difficult to find. Itching commonly occurs in locations where there are no mites present. Extensive excoriations and secondary bacterial infections can cause puzzling skin lesions. Diagnosis is made by gentle scraping of the burrows with a scalpel blade covered with mineral oil. The mineral oil and scraped material are transferred to a glass slide, a

coverslip is applied, and the slide is examined under a microscope for mites, eggs, or feces. Persons who are immunocompromised (e.g., AIDS) or debilitated (especially elderly or institutionalized persons) may develop crusted hyperinfestation also called "Norwegian" scabies, in which hyperkeratotic crusted nodules and plaques become widespread on the body. Millions of mites may be present in this condition, making it extremely contagious. It is easily misdiagnosed as eczema or another condition. Other closely related scabies mites infest domestic animals, especially dogs (sarcoptic mange). These mites can bite humans and produce pruritic papular lesions without burrows. They cannot complete their life cycle on humans, so no specific anti-scabies treatment is needed (1).

TICKS

Among the biting arthropods, ticks are second only to mosquitoes in the number of pathogens transmitted to humans. There are four stages in the life cycle: egg, larva, nymph, and adult. Even in highly endemic areas, ticks are not evenly distributed. *Ixodes scapularis* is most likely to be found in brushy areas at the interface between fields and forests (forest boundaries), whereas *Dermacentor variabilis* prefers meadows and roadsides. They "quest" for host animals by climbing vegetation (few inches to 3 ft) and passively wait for a host to pass by. Ticks cannot fly, jump, or swim. Larvae, nymphs, and adult females (but not adult males) increase in size enormously during feeding. They are capable of withstanding environmental stresses, and adults may live for several years. The soft-bodied ticks feed and engorge within a few minutes. The hard-bodied ticks attach for many days; once attached, feeding (and transmission of disease) may not begin for several days. When feeding, they excrete large amounts of saliva and feces containing pathogens. Tick bites are usually painless, and there is often no reaction at the bite site after the tick is removed or drops off. Sometimes, a hypersensitivity reaction to the bite occurs, or a red nodule may persist at the bite site for weeks to months (2).

I. scapularis (deer tick or black-legged tick), transmits Lyme disease (*Borrelia burgdorferi*), anaplasmosis (*Anaplasma phagocytophilum,* a

rickettsia-like organism), babesiosis (*Babesia microti,* a malaria-like protozoan), and Powassan disease (a type of viral encephalitis) to humans (1,16). Lyme disease is most common in the northeastern and upper Midwest United States because the primary host for the tick's nymphal stage in these regions, the white-footed mouse, is capable of high rates of spirochetemia and is an excellent transmitter to ticks. The nymph, not the adult tick, most often transmits Lyme disease to humans; the nymphs are more likely to remain attached undetected for long periods of time because of their small size (about the size of a poppy seed or the head of a pin). Adult ticks, which primarily feed on deer and are the size of an apple seed, are also capable of transmitting infection but are more easily seen and removed before disease transmission occurs. Lyme transmission requires >24 hours of attachment for nymphs and 36 hours for adults. *Ixodes pacificus* (western black-legged tick), found in the western United States, transmits Lyme disease (but infection rates in the tick are very low owing to their feeding behavior) and anaplasmosis. Both nymphal *I. scapularis* and *I. pacificus* ticks in the southern and western United States have very low rates of infection with the Lyme disease organism (1). They feed primarily on lizards, which are incapable of infecting ticks, and they rarely bite humans. Lyme transmission from *I. pacificus* requires >96 hours of attachment for nymphs. *D. variabilis* (American dog tick) transmits Rocky Mountain spotted fever (*Rickettsia rickettsii*) in the eastern United States, with disease transmission requiring >24 hours of attachment (1,16). Only adults feed on humans. Only 1% to 5% of ticks in an endemic area are infected with the rickettsial organism. This tick also transmits tularemia (*Francisella tularensis*) and can cause tick paralysis (owing to a neurotoxin secreted by the tick). For tick paralysis to develop, the tick must remain attached for at least 5 to 6 days. *Dermacentor andersoni* (Rocky Mountain wood tick) transmits Rocky Mountain spotted fever in the western United States, tularemia, and Colorado tick fever (*Coltivirus*) and can cause tick paralysis. *Amblyomma americanum* (Lone Star tick), whose primary host is the deer, transmits tularemia, ehrlichiosis (*Ehrlichia chaffeensis,* a rickettsia-like organism), and STARI ("Southern tick-

associated rash illness"), a newly described Lyme-like disease in the southeastern United States, whose cause is undetermined (1,16). People disrobing or lying on the ground in heavily infested wooded areas may be attacked in great numbers by larval *A. americanum* ticks, causing hundreds of pruritic papules (17). *Amblyomma maculatum* (Gulf coast tick), common in the southeastern United States, has been reported to transmit *Rickettsia parkeri,* a newly described spotted-fever-group rickettsia producing a mild febrile illness accompanied by multiple eschars and a maculopapular eruption (1,16). The brown dog tick, *Rhipicephalus sanguineus,* transmits Rocky Mountain spotted fever in eastern Arizona (16) Q fever (*Coxiella burnetii*) can be acquired from inhalation of dead tick parts or feces in dust.

Ixodes, Dermacentor, and *Amblyomma* spp. are all hard-bodied ticks, and prolonged attachment is required for feeding and disease transmission. Hard ticks will remain attached for 7 to 14 days before dropping off (1).

In contrast, soft-bodied *Argasidae* ticks of the genus *Ornithodoros* bite, feed, and drop off within a few minutes and prefer animal burrows or manmade animal or human shelters (1,16). Nymphs and adults transmit tick-borne relapsing fever (*Borrelia hermsii* and other spp.) in rodent-infested cabins in the high mountains of the western United States, Canada, and Mexico. Humans are bitten when they sleep in infested cabins.

Other tick species in the United States bite humans but do not transmit disease (1). Ticks in other parts of the world transmit a host of diseases that are important to travelers, including rickettsial diseases such as Boutonneuse fever and African tick bite fever, and arboviruses causing encephalitis and hemorrhagic fever (11).

Table 374.1 lists the biting arthropods of medical importance in North America, their geographic distribution, and the diseases they transmit.

TABLE 374.1
Diseases Transmitted by Biting Arthropods in North America

Arthropod	Geographic Distribution of Arthropod	Disease Transmitted
Conenose bugs ("kissing bugs")	Southwestern US, Mexico	American trypanosomiasis
Mosquitoes	Widespread	Malaria, Dengue, Chikungunya, Arbovirus encephalitides
Deer fly	Widespread	Tularemia
Fleas	Widespread	Plague, Murine (endemic) typhus, Cat-scratch disease
Human body louse (*Pediculus humanus corporis*)	Sporadic	Epidemic typhus, Trench fever
House mouse mite (*Liponyssoides sanguineus*)	Northeastern US	Rickettsialpox
Ixodes scapularis (Deer tick, black-legged tick)	Southeast, mid-Atlantic, northeast, upper Midwest US	Lyme disease, Anaplasmosis, Babesiosis, Powassan disease
Ixodes pacificus (Western black-legged tick)	Far western US and Canada	Lyme disease, Anaplasmosis
Dermacentor variabilis (American dog tick)	Eastern, Midwest US, Mexico	Rocky Mountain spotted fever, Tularemia, Tick paralysis (neurotoxin)
Dermacentor andersoni (Rocky Mountain wood tick)	Rocky Mountains of US and Canada, Great Basin of US	Rocky Mountain spotted fever, Tularemia, Colorado tick fever, Tick paralysis
Amblyomma americanum (Lone Star tick)	Southeastern, mid-Atlantic US	Ehrlichiosis, Tularemia, STARI "Southern tick-associated rash illness"
Amblyomma maculatum (Gulf coast tick)	Southeastern US	Spotted fever-like illness with eschars (*R. parkeri*)
Rhipicephalus sanguineus (Brown dog tick)	Widespread	Rocky Mountain spotted fever (eastern Arizona only)
Ornithodoros species (soft ticks)	Mountains of western US, Canada, and Mexico	Tick-borne relapsing fever (Borrelia spp.)

DIFFERENTIAL DIAGNOSIS

Reactions to arthropod bites are difficult to diagnose, as many patients may be unaware or cannot remember any exposure. The pruritic papules, vesicles, pustules, nodules, and bullae resulting from allergic reactions to arthropod bites may easily be misdiagnosed as allergic or irritant reactions to drugs or chemicals, atopic or contact dermatitis, *Herpes simplex,* staphylococcal and other bacterial infections, or cutaneous fungal infections (1,2). Multiple linear papules or vesicles should suggest bites by bedbugs or chigger mites, whereas irregular groups of papules and vesicles are typical for fleas and chiggers. Lesions caused by mosquitoes are multiple and scattered, not linear or grouped. A deer or horse fly bite that becomes secondarily infected and forms an ulcer could be misdiagnosed as a brown recluse spider bite. Arthropod bites and

infestations should also be considered in the differential diagnosis of any patient complaining of itching. “Insect bites” should generally not be diagnosed upon the basis of lesions alone. Scabies should be considered in the differential diagnosis of patients presenting with scattered pruritic papules, especially when found on the hands, wrists, elbows, and genital areas. Crusted “Norwegian” scabies should be considered in the differential diagnosis for immunosuppressed or debilitated patients presenting with subacute or chronic widespread hyperkeratotic plaques or eczematous lesions, even in the absence of pruritus. Scabies can easily be misdiagnosed as eczema, contact dermatitis, psoriasis, fungal infection, adverse drug reaction, senile pruritus of the elderly, “pruritus of AIDS,” and many other conditions.

An arthropod-borne infection should always be considered in the differential diagnosis of persons presenting with an acute febrile illness (10). The patient should be questioned about travel to endemic areas or outdoor exposures. Lyme disease or rickettsial infections may but not always, have a characteristic rash (11,16). Tick paralysis, which may be confused with Guillain–Barré syndrome, botulism, or spinal cord compression, presents initially with restlessness, irritability, paresthesias, and ataxia followed by rapidly progressive ascending flaccid paralysis, with a normal sensory examination, a clear sensorium, and lack of fever. Tick paralysis is especially likely in children and in girls, in whom the ticks are often concealed in long hair at the nape of the neck. Patients with pubic lice should be screened for sexually transmitted diseases.

Patients suffering from delusions of “parasitosis” have an unwarranted belief that live organisms, such as mites or insects, are present on the body (18,19). The typical patient is a well-educated, responsible, hard-working woman who may have an excessive preoccupation with cleanliness and has a single delusion and no other mental disorder. This belief often persists for many years despite numerous physician visits and repeated treatments of the house with pesticides and the patient by medication, usually physician-prescribed. Typical characteristics of the “bugs” include

that they change color; they jump; they appear and disappear while being watched; they enter the skin and reappear; they invade the hair; nose and ears; they infest the patient's hair, and can be combed or shaken onto a sheet or towel; and they sometimes come out of common household items (toothpaste, cosmetics) or teeth after brushing. Family members often support the patient but are never afflicted. Patients typically bring in samples of the supposed pest for examination, which consist of small bits of lint, cloth, dandruff, or scabs. These patients should be referred to a dermatologist to definitively rule out an infestation and to a psychiatrist, although the patients will generally not accept any suggestion that this is "all in their head." An entomologist may also need to be consulted (1). Delusions of parasitosis known as "cocaine bugs" may also be seen in persons abusing cocaine and amphetamines and in patients with schizophrenia, depression, anxiety disorders, and neurologic disorders.

ED EVALUATION

The emergency physician should be familiar with the biting insect, mite, and tick fauna in the local area. A complete history should include travel, outdoor activities, any known exposures to biting arthropods, and medications already used as these could affect or change the appearance of lesions (1). Patients complaining of itching or papules in the scalp or genital area should be asked about household or sexual contacts that may have head lice or pubic lice and should be examined carefully for adult lice and nits attached to the hair shafts. The skin should be examined carefully for evidence of bites, allergic reactions, secondary bacterial infections, burrows of scabies, or rashes typical for infections transmitted by arthropods.

KEY TESTING

- Skin scrapings for scabies
- Low power microscopic examination of suspected lice
- Serologic testing and stains for various virus, rickettsia, bacteria, and protozoa causing systemic illness
- Skin examination for embedded ticks

ED MANAGEMENT

Pruritic skin lesions should be treated with cold compresses, soothing lotions, topical corticosteroids, and systemic antihistamines. Systemic allergic reactions may require treatment with epinephrine, intravenous fluids, systemic corticosteroids, and antihistamines. Secondary bacterial infections, often seen with deer or horse fly bites or with excoriated mosquito or flea bites, are usually caused by *S. aureus* or *Streptococcus pyogenes* and should be treated with appropriate antimicrobial agents. A wound culture should be obtained for serious local infections, and empiric therapy for MRSA should be considered, and tetanus immunization should be given if needed. Patients who present with undifferentiated fever with or without generalized rash, rash without fever, or signs of encephalitis after an arthropod bite may require investigation for one of the many viral, rickettsial, or bacterial infections transmitted by these creatures (10,11).

Resistance of lice to topical pediculicides has increased dramatically (13,14). The Centers for Disease Control and Prevention recommends treatment of head lice only if live lice are detected or if nits are found attached to hair shafts less than one-quarter inch from the scalp (14). Of the topical agents available for treatment, malathion lotion 0.5% (not recommended in children younger than 2 years of age), and ivermectin lotion 0.5% (not recommended for children younger than 6 months of age), are the most effective; lindane is the least effective; and permethrin and pyrethrins are intermediate in effectiveness (20,21). If pyrethrins (combined with piperonyl butoxide) or permethrin lotion 1%, both available without prescription in the United States, are used, a second application should be done 7 to 10 days later. A second application of malathion may be needed 7 days later. Use of a fine-toothed comb on wet hair is recommended to remove nits. Lindane, which is banned in California, should be avoided because of neurotoxicity, high resistance rates, and the potential for contaminating the environment. Two other topical agents, benzyl alcohol lotion 5%, and spinosad suspension 0.9%, available by prescription only in the

United States, are also effective, but repeat treatments may be necessary. Oral ivermectin (not FDA-approved for this indication) is an alternative when topical treatments fail (22). Mechanical removal of lice with repeated wet combing every 3 to 4 days by parents is an alternative to malathion but is not nearly as effective. “Natural” herbal and chemical products marketed for treatment of lice are not effective and may be unsafe. Bedding, clothing, and towels used by the infested person in the 2 days prior to treatment should be washed and dried at high temperatures, dry cleaned, or kept in sealed plastic bags for 2 weeks. Household contacts of patients with head lice and sexual partners of those with pubic lice should be examined for lice and nits every 2 to 3 days and treated only if crawling lice or nits within one-quarter inch of the skin are found. Many schools routinely exclude children for head lice, but this practice is not recommended by the American Public Health Association.

Scabies should be treated with permethrin 5% cream applied to all areas of the body from the neck down and washed off after 8 to 14 hours, usually with a second treatment 1 week later recommended (15). Topical crotamiton 10% cream is safe for newborn babies and infants but is less effective than permethrin. Lindane-resistant scabies is now widespread in the United States. Ivermectin 200 μg/kg orally in a single dose for adults is effective in resistant cases, with a second dose 2 weeks later usually recommended (15,21,23). It is not FDA-approved for this indication, but its use is recommended by the Centers for Disease Control and Prevention, and by The Medical Letter, as an alternative agent. Crusted (“Norwegian”) scabies in debilitated or immunocompromised patients should be treated with topical keratolytic agents followed by repeated doses of total-body permethrin cream and oral ivermectin. An alternative treatment for pregnant and lactating women and children younger than 2 months is precipitated sulfur 6% in petrolatum, but there is little evidence for efficacy or safety. Itching may continue for up to 4 weeks after curative therapy and is not an indication for repeat treatment. Bedding, clothing, and towels used in the previous 48 to 72 hours should be washed and dried at high temperatures or dry cleaned or stored in sealed plastic bags for the same period of time.

The best method for preventing infection with tick-borne pathogens is to avoid exposure to ticks. If exposure is unavoidable, measures to reduce the risk of infection include the use of protective clothing and tick repellents, checking the entire body daily for ticks, and prompt removal of attached ticks. To remove an attached adult tick, the tick should be grasped with blunt curved forceps, narrow tweezers, or gloved fingers as close to the point of attachment as possible, then pulled firmly and steadily in the direction of attachment. Some back-and-forth motion may be needed, but the tick should not be twisted. If the tick's head breaks off in the skin, use tweezers to remove it. Disinfect the bite site and wash hands thoroughly. This method is most effective for the large adults of *Dermacentor* and *Amblyomma* tick species but may not be effective for adult *Ixodes* ticks or larval ticks of any species, which are much smaller. Application of viscous lidocaine 2% may be effective for these smaller adults or larval ticks. Application of isopropyl alcohol, petroleum jelly, a hot match, fingernail polish, or use of sharp forceps should be avoided, as this may cause the tick to salivate or regurgitate and increase the potential for disease transmission. Two other anecdotal methods of tick removal have been suggested: using a disposable razor to shave off the tick's body without squeezing the tick, and using cryospray with liquid nitrogen to instantly freeze the tick, then wiping it off or removing it in toto, but these methods and application of viscous lidocaine have not been subjected to clinical trials (24). An entomologist should be contacted if it is important to identify a tick or other biting arthropod that has bitten a person. The Centers for Disease Control and Prevention website on ticks at www.cdc.gov/ticks is an excellent resource on ticks found in the United States, including color pictures, geographic distributions, diseases transmitted by ticks, tick avoidance, tick removal methods, and tick life cycles.

Although some practicing physicians routinely prescribe antimicrobial agents to persons who have been bitten by ticks in areas highly endemic for Lyme disease, most experts believe that routine antimicrobial prophylaxis or serologic testing after a tick bite is not necessary (1,25). The risk of acquiring Lyme disease or any

other tick-borne infection after a tick bite is quite low, even in highly endemic areas. Doxycycline 200 mg orally in a single dose for adults may be effective in preventing Lyme disease in a highly endemic area if the tick is at least partially engorged or attached for greater than 72 hours. The Infectious Diseases Society of America recommends prophylaxis with single-dose doxycycline 200 mg for nonpregnant adults and children at least 8 years of age (4 mg/kg for children; maximum, 200 mg) only when all of the following are met: (a) The tick can be identified as an adult or nymphal *I. scapularis* tick that is likely to have been attached for >36 hours based on the degree of tick engorgement with blood or confidence about the time of exposure to the tick; (b) prophylaxis can be started within 72 hours of the time that the tick was removed; (c) the local rate of infection of ticks with *B. burgdorferi* is >20%; and (d) doxycycline is not contraindicated (25). Infection of >20% of ticks with *B. burgdorferi* is found in parts of New England, the mid-Atlantic states, Minnesota, and Wisconsin but is rare in other locations in the United States. Although amoxicillin is an effective treatment for early Lyme disease and is the preferred agent for pregnant women and children younger than age 8, there is no evidence that it is an effective preventive agent after a tick bite. There is no evidence that antimicrobial treatment is effective in preventing other tick-borne infections in the United States, and it is not recommended.

Tick paralysis is treated supportively. A rapid and complete recovery occurs after removal of the tick.

CRITICAL INTERVENTIONS

- Recognize that serious allergic reactions including anaphylaxis may be the result of arthropod bites, even when no arthropod was seen.
- Check the skin and scalp for ticks in patients with rapidly progressive ascending flaccid paralysis, particularly children and those with a normal sensory examination, clear sensorium, and no fever.
- Treat secondary bacterial infections with appropriate antimicrobials, with consideration for community-associated

MRSA.
- Institute infection control measures and offer treatment to those who have had close unprotected contact with patients with scabies.
- Consider an arthropod vector-borne disease in the differential diagnosis of an acute febrile illness in the appropriate circumstances, regardless of whether the patient has a rash or remembers a bite.

DISPOSITION

Almost all patients suffering from arthropod bites can be discharged unless they have life-threatening anaphylaxis or serious secondary bacterial infections of skin lesions or are suspected to have a serious arthropod-borne systemic infectious disease or tick paralysis. Patients should be advised to avoid tick-infested areas. If exposure is unavoidable, the use of protective clothing, wearing light-colored clothing (making it easier to spot ticks), daily inspections of the entire body with prompt removal of ticks, and application of tick and insect repellants to skin and clothing are recommended (1). Permethrin aerosol spray is very effective when used on clothing and tents but should not be applied to the skin. DEET is the most effective insect repellent that can be applied to the skin, and it repels a variety of mosquitoes, chiggers, ticks, fleas, and biting flies (1). Picaridin is an alternative effective insect repellent. Persons who have been bitten by ticks should be advised to promptly seek medical attention if they develop a fever or a skin lesion at the site of the bite up to 30 days later.

Common Pitfalls

- Failure to obtain a history of travel or exposure to environments where biting arthropods are present.
- Failure to recognize that an acute febrile illness, with or without generalized rash, may be caused by an arthropod vector-borne infection.

- Failure to screen for sexually transmitted diseases in persons with pubic lice.
- Misdiagnosis of scabies as eczema, contact dermatitis, fungal infection, psoriasis, nonspecific pruritus or other conditions, and failure to treat household contacts of patients with scabies.
- Routinely prescribing antibiotics to patients with reported tick bites.

CHAPTER 375

Mammalian Bites and Associated Infections

Johanna C. Moore

Mammalian bite wounds, including dog, cat, and human bites, account for up to 1% of all visits to emergency departments (EDs). A majority of bite wounds are superficial and over 70% of patients are bitten by an animal known to them.

The majority of animal bites are from dogs. Dogs bite approximately 4.7 million persons in the United States every year. Nearly 20% of those sustaining dog bites seek medical attention, 1% to 2% require hospitalization and about 20 people die per year from their dog bites (1,2). Of those dog bites requiring medical attention, children are disproportionately affected; with 60% to 75% less than 20 years old and a majority are 5 to 9 years old. Males are more likely to be bitten, and in children, the face is frequently affected (1,3). Cat bites account for 3% to 15% of all animal bites and primarily affect the arms and face. Females are more likely to be affected (4).

Human bites account for up to 3% of bite wounds (3). Although less common than dog and cat bites, they have a higher complication and infection rate than animal bites. In children, most bite wounds occur while playing or fighting. Many human bites occur during an altercation, with the majority of bites located on the hands, fingers, or extremities in adults. Young males are at higher risk to sustain human bite injuries (5,6). Occupational exposure can occur in dental professionals, caretakers of the mentally impaired, daycare workers, and medical personnel involved in airway

management of the care of seizing or combative patients. “Love bites” often involve the neck, breasts, or genitalia, during passionate sexual encounters. Clenched-fist injuries (“fight bites”), which occur when a fist strikes teeth during an altercation, are among the most serious of human bites. The microbes contained in plaque and deposits around teeth may be carried to deep structures and relatively avascular tissue planes. The patient can present with an innocuous-appearing laceration, often with an initial alternative explanation of the mechanism of injury. These bites, however, are at risk for development of tenosynovitis, septic arthritis, or osteomyelitis. Tendon laceration, fracture, joint injury, or retained foreign body may occur as a result of the immediate injury.

Approximately 2% to 6% of dog bite wounds seen in the ED become infected, however, wounds extending through the dermis have a higher rate of infection at 6% to 13% (7). Cat bites have a higher rate of infection than dog bites, with cited rates at 30% to 50% (5), presumably due to sharper teeth and the deeper puncture wound usually sustained. Overall rates of human bite infection have been cited at 10% to 20% (6). Hand wounds from human bites have the highest rate of infection, up to 30% to 50% in some studies (3,8,9). However, a 2004 study of low-risk human bites, found an infection rate of 1.6% (10).

Important pathogens causing dog, cat, and human bite infections are often a mix of both aerobic and anaerobic pathogens. Pathogens include oral flora from the biter and skin flora from the patient. Pasteurella (*Pasteurella canis, Pasteurella multocida, Pasteurella septica*) is a frequent isolate in both dog bites (50%) and cat bites (75%) and commonly seen in abscesses and puncture wounds. Other common aerobes isolated are streptococci (46%), staphylococci (20% in dogs and 4% in cats), moraxella, and neisseria. Anaerobic bacteria include fusobacterium, bacteroides, porphyromonas, and prevotella (11,12). A significant pathogen found in dog bites is *Capnocytophaga canimorsus,* which can cause severe systemic infection, disseminated intravascular coagulation, or meningitis in the immunocompromised. This infection is traditionally thought of

in the asplenic or alcoholic patient, although infections are also reported in healthy hosts.

Human bite wound pathogens also include both aerobic and anaerobic bacteria. Streptococci and staphylococcus species are the most common isolates. Common anaerobic isolates include Eikenella, Fusobacterium, and Prevotella (13). Community-acquired methicillin-resistant *Staphylococcus aureus* (ca-MRSA) is now recognized as an increasingly common pathogen with a prevalence of up to 55% in a study of hand infections (14).

The organism responsible for cat-scratch disease, *Bartonella henselae,* can be transmitted from a cat bite or scratch, and also by a flea bite. Cats are the main reservoir for *B. henselae,* with bacteremia that can persist up to a year or even longer. The gram-negative organisms *Streptobacillus moniliformis* and *Spirillum minus* can cause rat-bite fever, commonly transmitted by a bite or via feces or secretions such as urine or mucous from an infected rodent.

Transmission of the human immunodeficiency virus (HIV) by human bite is rare but has been reported, usually in association with bloody saliva (15). The risk of transmission should be addressed on an individual basis. Exposure to saliva alone is not considered a significant risk factor and the skin must be broken for bloody saliva to be considered a significant exposure (5). Transmission of hepatitis B (HB) via human bite has been reported, with evidence that up to 75% of HB patients have detectable antigen in their saliva. Herpesvirus simiae (B virus), carried by rhesus and other macaque monkeys can spread to humans by bites or scratches and can lead to fatal encephalitis (8).

Rabies, caused by a variety of viral species within the genus Lyssavirus, is transmitted by the saliva of an infected animal. All mammals are thought to be susceptible to rabies, however the major reservoirs of rabies in the United States include bats, raccoons, skunks, and foxes (16). The majority (99%) cases of human rabies occur in countries where rabies is endemic, with much higher rates in Africa, Southeast Asia, and India. There are one to three annual cases of human rabies in the United States, which occur primarily

from bat exposure. Rabies transmission from domestic animals in the United States, Europe, and Canada is rare (3).

CLINICAL PRESENTATION

Animal bites can lead to trauma of the skin, tendons, joints, bones, major vessels, viscera, brain, and other organs. Immediate death from a bite is rare but usually a result of hemorrhagic shock. The visible wounds from a bite can vary greatly and include lacerations, punctures, abrasions, and avulsions. The clinician should have a high suspicion for clenched-fist injury when taking care of wounds over dorsum of the proximal phalanges or metacarpophalangeal joints, even if patients do not give this history. Patients who present more than 24 hours after injury are more likely to have signs of established local or systemic infection.

Cat-scratch disease, most common in children, usually begins with a papule or vesicle that develops at the bite or scratch site around 1 week after exposure. However, patients may not notice or give thought to the primary bite or rash. The characteristic regional tender lymphadenopathy of the disease develops proximal to the bite site approximately 2 weeks after inoculation. Less commonly, cat-scratch disease can have neurologic, ocular, and visceral involvement in immunocompetent patients, and should also be considered in fevers of unknown origin (17).

Patients with rat-bite fever from *S. moniliformis* typically develop sudden fever, headache, arthralgias, and myalgias several days (range of 1 to 22 days) after a bite or scratch from an infected rat, handling an infected rat, or ingestion of rat excreta. A rash (macular, petechial, purpuric, or pustular; centripetal or generalized) and asymmetric polyarthralgia or arthritis may also be present. Complications include bacteremia, soft tissue abscesses, meningitis, pneumonia, septic arthritis, and endocarditis (18).

The presentation of human rabies varies with the time elapsed after exposure. An asymptomatic incubation period is generally 3 to 12 weeks with a range of several days to months, followed by a nonspecific prodrome of 2 to 10 days of nonspecific symptoms such

as fever, headache, nausea, vomiting, and malaise. Pain and paresthesias of the initial bite wound or affected limb may be present. There may be evidence of wound infection. The ensuing acute neurologic phase lasts 2 to 10 days. In about 80% of cases, the "furious" or encephalitic rabies, signs of hyperactivity predominate; these include agitation, autonomic instability, hallucinations, thrashing, biting, and the classic hydrophobia or aerophobia caused by an exaggerated respiratory-tract protective reflex. In the remaining 20% of cases, called paralytic or "dumb" rabies, ascending paralytic signs predominate with intact sensorium. The prognosis of rabies is invariably fatal, with few case reports of survivors noted, and a majority of deaths occur after 2 weeks after coma onset (16).

DIFFERENTIAL DIAGNOSIS

With the exception of clenched-fist injuries, the history of patients presenting with animal bites is rarely obscure, and the differential diagnosis revolves primarily around determining the presence or absence of concomitant infection and underlying tissue injury.

The differential diagnosis of cat-scratch disease and rat-bite fever is extensive. The differential in cat-scratch disease mostly includes other causes of infectious causes of lymphadenopathy such as cytomegalovirus, Epstein–Barr virus, HIV, mycobacterium, streptococcal or staphylococcal adenitis, and toxoplasmosis. Malignancy such as lymphoma or leukemia should also be considered (17). The differential for rat-bite fever includes sepsis from bacteria such as *S. aureus, S. pyogenes, N. meningitides,* or *N. gonorrhoeae,* Lyme disease, Ehrlichiosis, Brucellosis, Rocky Mountain spotted fever, leptospirosis, and secondary syphilis. Viral illnesses include Epstein–Barr, parvovirus, and coxsackie. Alternate causes of relapsing febrile illness include malaria, typhoid, and *Borrelia recurrentis.* Noninfectious processes are drug reactions or collagen vascular disease.

Rabies must be differentiated from other infectious causes of encephalitis, including herpes, arboviruses (including West Nile

virus), tetanus, malaria, rickettsia, typhoid, poliomyelitis, and botulism. Noninfectious diseases that must be considered include Guillain–Barré syndrome, poisoning, alcohol withdrawal, acute porphyria, and behavioral disorders.

ED EVALUATION

Initial evaluation of acute injuries should include a primary survey, with attention to the basics of trauma care. The history should include details of the biting event: the time, the offending animal, and its identity (wild or domestic, immunization and health status, captured or not), and the nature of the attack (provoked or unprovoked). The patient's underlying health status, and compromised immunity should also be determined. The patient should be assessed not only for skin wounds but also for deep-structure injury, particularly of the brain, vessels, viscera, nerves, tendons, joints, bones, and spinal cord. Puncture wounds are particularly prone to cause deep and often undiagnosed injuries. Location of the wound on the hand, wrist, foot, or joint of a patient or on the face and scalp of an infant increases the likelihood of deep-structure injury.

Radiographs of the injured area should be considered for suspected foreign body or fracture. Skull radiographs and computed tomography (CT) scanning of the head and cervical spine are indicated for infants with significant face and scalp bites.

Cultures from clinically infected wounds should be obtained. Although Gram stain and culture of fresh bites do not predict infection, a Gram stain and culture (aerobic and anaerobic) may be helpful in clinically infected wounds. If sepsis is suspected, the Gram stain of the peripheral blood should be examined for evidence of *C. canimorsus,* and blood cultures (anaerobic and aerobic) should be obtained. With serious infection, complete blood count; blood urea nitrogen, glucose, electrolyte, and creatinine levels; prothrombin time; partial thromboplastin time; fibrin split products; and lumbar puncture with cerebrospinal fluid (CSF) analysis and culture may be helpful. Antibody titers (acute and convalescent) may be necessary.

KEY TESTING

- Bite wounds do not benefit from laboratory testing unless to help define the severity of an established infection.
- Strongly consider radiographs and/or CT scan in infants with significant face or scalp bites.
- Consider radiographs for fracture and/or retained foreign body.

ED MANAGEMENT

Beyond the initial primary and secondary surveys that should be performed, imperative to mammalian bite management is good wound care. A sensory and motor examination should be performed prior to any anesthesia. The wound should be cleansed with soap and water initially, and then the wound copiously irrigated (250 mL–1000 mL or more as indicated) with saline or tap water under high pressure. Solutions such as povidone-iodine, ethyl alcohol, and hydrogen peroxide can cause additional injury and should be avoided for irrigation. A full exploration of the wound should be performed, paying particular attention to possible foreign body (teeth), vessel, bone, tendon, or joint injury. If the bite occurred over a joint, the wound should be visualized over the full range of motion. Debridement may be performed for removal of devitalized tissue. If the clinician chooses to close the wound, deep sutures should be avoided as they may lead to higher rates of infection. Wounded extremities should be immobilized and elevated.

Facial wounds should be primarily closed with concurrent antibiotic administration to minimize scarring. This approach has been shown to be safe in children (19). Primary closure of other wounds, particularly the extremities, are controversial with some authors advocating no primary closure (4,12). There is limited evidence on this topic. In a single randomized controlled trial of primary wound closure versus no closure for dog bites, there were no overall significant difference in rates of infection. There was a significantly higher rate of infection in the hand overall with no difference between primary closure and wounds left open. Excluded were puncture wounds, clinically infected wounds, wounds

requiring plastic surgery or involving nerve, tendon, bone, or joints, and no prophylactic antibiotics were given (20). Delayed primary closure is also a good option if the clinician is unsure whether to primarily close.

Prophylactic antibiotic therapy for dog, cat, and human bites is controversial. Prospective controlled trials examining outcomes of mammalian bite wounds with and without prophylactic antibiotics are scarce. Rates of infection without prophylactic antibiotics vary widely between studies when taking the species, wound type, and location into account. The development of a bacterial infection following a bite wound depends on multiple factors including the species (human bites are at higher risk), possibly the type of wound, location of wound (hands are at higher risk), the type of wound care provided, and comorbidities of the individual (age, presence of immunocompromised conditions) (21).

Based on the limited evidence available and expert opinion, antibiotic prophylaxis for human or cat bites is most appropriate for bites to the face, hands, feet, skin overlying joints, or cartilaginous structures, crush wounds, puncture wounds, sutured wounds, wounds with a large amount of devitalized tissue, dirty wounds, and for bites that extends beyond the epidermis (Table 375.1) (3,8,21–23). The utility of prophylactic antibiotics for dog bites is unclear. Minor bites that occurred within 24 hours, or involve only epidermal stripping, scratches, and abrasions are less likely to benefit from antibiotic prophylaxis (3). Some authors advocate for antibiotic treatment for all bite wounds, except in patients who present 72 hours or more after injury and have no signs of infection (8).

TABLE 375.1
Indications for "Prophylactic" Antibiotics[a]

Wound	Patient	Source
Puncture	Age (<2 yrs, >50 yrs)	Human
Crush	Asplenic	Cat
Old (>8 hrs)	Alcoholic	Primate
Extremity (especially hand)	Diabetic	Pig
Sutured	Otherwise immunocompromised	

[a]Adapted from Cummings PC. Antibiotics to prevent infection in patients with dog bite wounds: A meta-analysis of randomized trials. *Ann Emerg Med*. 1994;23:535; Medeiros I, Saconato H. Antibiotic prophylaxis for mammalian bites. *Cochrane Database Syst Rev*. 2001;(2):CD001738; and Morgan M, Palmer J. Dog bites (clinical review). *BMJ*. 2007;334(7590):413.

Antibiotic therapy for infected dog, cat, and human bites should cover Pasteurella, Eikenella, streptococci, staphylococci, and anaerobes. First-generation cephalosporins, dicloxacillin, and erythromycin should be avoided due to poor coverage of Pasteurella and Eikenella (11). Based on expert opinion and the evidence available, amoxicillin and clavulanic acid are the recommended first-line agents for mammalian bite prophylaxis and treatment of ambulatory infections (4,8,11,13). Alternative regimens include a **combination** of an extended-spectrum cephalosporin, trimethoprim/sulfamethoxazole, doxycycline, penicillin VK, moxifloxacin for Pasteurella coverage, **and** metronidazole or clindamycin to cover anaerobes (Table 375.2).

TABLE 375.2
Oral Antibiotics for Treating or Preventing Mammalian-Bite Infections[a]

Antibiotic	Comments
Current Drug of Choice	
Amoxicillin-clavulanic acid (875 mg twice a day)	No activity against CA-MRSA. Safe in pediatrics.
Alternate Regimens	
Clindamycin PLUS second- or third-generation cephalosporin (cefuroxime, cefpodoxime)	Reasonable activity against CA-MRSA. Safe in pediatrics.
Cefoxitin	No activity against CA-MRSA. Safe in pediatrics.
Clindamycin PLUS fluoroquinolone (ciprofloxacin, moxifloxacin)	Safe in penicillin allergic adults. Reasonable activity against CA-MRSA.
Doxycycline PLUS Metronidazole	Safe in penicillin allergic adults. Reasonable coverage of CA-MRSA.
Clindamycin PLUS trimethoprim-sulfamethoxazole	Safe in penicillin allergic patients and pediatrics. Reasonable coverage of CA-MRSA.
Clindamycin PLUS penicillin VK	Reasonable coverage of CA-MRSA.

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*.
[a]Adapted from Talan DA, Abrahamian FM, Moran GJ, et al. Clinical presentation and bacteriologic analysis of infected human bites in patients presenting to emergency departments. *Clin Infect Dis*. 2003;37; and Talan DA, Citron DM, Abrahamian EM, et al. Bacteriologic analysis of infected dog and cat bites. *N Engl J Med*. 1999;340:85; Brook, I. Management of human and animal bite wound infection: An overview. *Curr Infect Dis Rep*. 2009;11:389–395; and Esposito S, Picciolli I, Semino M, et al. Dog and cat bite-associated infections in children. *Eur J Clin Microbiol Infect Dis*. 2013;32:971–976.

For patients who require parenteral therapy, monotherapy of intravenous ampicillin/sulbactam, piperacillin-tazobactam, or a carbapenem should be used as first-line antimicrobials (4). Dual therapy with a third-generation cephalosporin or a fluoroquinolone plus an anaerobic agent such as metronidazole can also be given. Coverage for MRSA should be considered, especially if the patient is at risk for ca-MRSA. Colonization and transmission of MRSA by pets have been reported (24).

The duration of antibiotic therapy should be tailored to the individual, based on the location of the wound, any culture results, and response to treatment. A 7- to 14-day course of antibiotics is generally adequate. A longer duration will be needed for infection of bone or joints (8). A shorter course of 4 to 5 days is appropriate for prophylaxis.

Cat-scratch disease resolves spontaneously in 1 to 2 months or may resolve sooner if treated with azithromycin (10 mg/kg, up to 500 mg on day 1; then 5 mg/kg, up to 250 mg daily for 4 more days). Uncomplicated rat-bite fever should be treated with penicillin (1.2 million units per day IV for 5 to 7 days) followed by oral penicillin or ampicillin (500 mg four times daily for 7 days). Alternatively, tetracycline (500 mg four times daily) or streptomycin (7.5 mg per kg twice daily) can be used.

The HB vaccination status of the patient should be determined. If the patient has sustained an exposure to HB-infected saliva or blood, he is potentially at risk for seroconversion, although this is rare. If a patient has a possible exposure to HB-infected blood or saliva, HB vaccination or rarely HB immunoglobulin can be offered, depending on the vaccination status of the patient and the exposure source (5). The tetanus status of the patient should be reviewed and updated if needed. The rabies vaccination status of the animal should also be determined. Rabies is almost always fatal, and prevention depends on control of exposure, aggressive local wound care, and knowledge of transmission, which is usually by means of saliva contacting a laceration, scratch, abrasion, or mucous membrane. Postexposure prophylaxis is indicated if the offending animal is known or clinically suspected to be rabid or if it is a bat or wild carnivore. The silver-haired bat variant of rabies virus is able to replicate in the superficial dermis and has been associated with several recent cases of human rabies without known history of conventional exposure. For this reason, postexposure prophylaxis is recommended for persons who may have come in contact with a bat (e.g., an infant or a sleeping adult in a room with a bat, even if a bite or scratch wound is not apparent). Livestock and unprovoked dog and cat bites should be considered individually in consultation with public health officials (16).

Patients bitten by healthy dogs and cats do not require rabies prophylaxis, provided that the animal can be located and observed for 10 days for signs of illness. Rabbit and rodent (e.g., hamster, mouse, rat, and squirrel) have not been known to transmit the disease and bites do not require treatment. Patients who have not

been previously immunized should receive both human rabies immune globulin (20 IU/kg) at or near the bite site and the remainder given IM at a distant site and human diploid cell rabies vaccine (1 mL IM in the deltoid or anterolateral thigh but not gluteal area, on days 0, 3, 7, 14). Patients previously immunized need not receive rabies immune globulin but should be given a booster series of human diploid cell vaccine (1 mL IM, not gluteal, on days 0 and 3).

DISPOSITION

The vast majority of patients can be treated as outpatients and return for worsening of infection. Clenched-fist injuries with involvement of tendon, joint, or bone should be considered for admission. All patients who do not require admission should be rechecked in 24 to 72 hours for signs of infection. If signs of infection develop, sutures must be removed and the wound must be left open for drainage.

Those who require IV antibiotics (e.g., systemic, central nervous system, hand, joint, or other deep-structure infection or any infection in a high-risk patient) or who cannot receive proper care as outpatients should also be admitted. In the rare cases of septicemia or in cases of possible HIV or HB or C transmission, consultation with an infectious disease specialist and a microbiologist (for a careful search for organisms unique to animal bites). A surgeon (general, hand, plastic, or orthopedic, depending on local practices) should be consulted when there is violation of a deep structure (such as a joint, bone, tendon, or internal organ), extensive facial damage, tissue loss, or a clenched-fist bite.

Infants, some children and the very rare adult who sustain major trauma, significant blood loss, or injuries that require operative intervention need to be admitted. Transfer to another institution should be arranged whenever appropriate inpatient facilities or consultants are unavailable.

Bites by potentially rabid animals should be reported to state public health officials or local animal control officers.

Common Pitfalls

- Failure to diagnose joint penetration, tendon injury, retained foreign body.
- Failure to close facial wounds that are at low risk for infection.
- Failure to consider clenched fist injury in a patient that does not offer this history.
- Failure to provide rabies immunization after possible bat exposure.
- Failure to identify and admit infected immunocompromised patients.

ACKNOWLEDGMENT

The author gratefully acknowledges the previous contributions of Stephen J. Playe to the content of this chapter.

SECTION XXV
EMS and Special Clinical Considerations

Section Editor: CARLO L. ROSEN

PART 1 • PREHOSPITAL CARE

CHAPTER 376

Emergency Medical Services

Alexander P. Isakov, Marc Restuccia, and Lawrence Mottley

HISTORICAL PERSPECTIVE

Prior to the rapid evolution of emergency medical services (EMS) in the 1960s and 1970s, only rudimentary systems of prehospital care and patient transport existed. Although hospital-based ambulance services had been functioning in Cincinnati, Ohio since 1865 and city services were initiated in New York in 1869, private ventures that combined transport services with another trade, such as funeral services, had the greatest market share. Such enterprises delivered prehospital care with little training, regulation, or benchmark for quality. The military advanced EMS in its care of wounded soldiers in Vietnam. Corpsmen and medics were trained in prehospital intervention and evacuation of the critically wounded to appropriate facilities for prompt surgical attention. The mortality of trauma patients surviving to a medical treatment facility sharply decreased.

In 1966, the National Academy of Sciences–National Research Council, which acts as a consulting body to the government, published what has been referred to as the "white paper" of prehospital systems, "Accidental Death and Disability: The Neglected Disease of Modern Society." This document summarized the inadequate delivery of emergency care, the lack of an emergency services infrastructure, and the lack of leadership in this area. It also made specific recommendations for a funded, organized, proactive, prehospital medical delivery system, launching the modern era of civilian EMS in the United States.

That white paper, along with others showing a rise in accidental deaths, especially on America's highways, prompted Congress to enact the National Highway Safety Act of 1966. This act authorized spending by the newly created Department of Transportation (DOT)/National Highway Traffic Safety Administration (NHTSA) for the improvement of essential prehospital infrastructure, training of personnel, and establishment of practice guidelines. Through this legislation, states developed regional EMS systems with funding for ambulances, personnel, and communication equipment. A nationally recognized curriculum for the training of ambulance attendants (emergency medical technician [EMT-A]) was established in 1971.

The success of prehospital cardiac care units in Dublin and of new methods of cardiopulmonary resuscitation (CPR) led EMS programs to expand their focus beyond trauma. The Department of Health, Education, and Welfare funded regional EMS demonstration projects in five states, and the Robert Wood Johnson Foundation offered grants for regional EMS development. The resulting improved communications, training, and transport capacity in these demonstration projects was viewed favorably in Congress and was followed by the EMS Systems Act of 1973, which legislated further federal funding of comprehensive regional EMS systems; this included money for operations, training, and research. Full-time medical directors and professional prehospital medical providers emerged.

National standards for EMT-A, EMT-I (intermediate level), and EMP-P (paramedic level) training evolved. Because some nonmedical public safety personnel were often the first to arrive at a scene with medical casualties, a first-responder curriculum was developed as well. NHTSA established such curricula, which came to be recognized as national standards.

Communications infrastructure, including 911 access, two-way radio communications, and centralized dispatch were developed, and criteria for optimal ambulance design and equipment were established. Regional EMS systems were intended to become financially independent as federal funding was phased out in favor of state discretionary funding of EMS through Preventive Health Block

Grants, a product of the Omnibus Budget Reconciliation Act of 1981. The result, however, was deterioration of the movement toward national standards as regional systems yielded to state and local concerns. A multitude of systems developed independently, providing a varied range of skill levels, training, and quality of care from one community to another.

Nationally, organizations like the National Association of EMS Physicians and the National Association of EMTs emerged to serve as professional bodies for consensus in the continuing development of EMS systems. At the federal level, the DOT maintained a leadership role through its Office of EMS at the NHTSA; however, EMS-related programs subsequently developed in a scattered fashion across many departments (i.e., the Department of Health and Human Services and the Department of Homeland Security). The absence of a single federal agency with the ability to comprehensively represent EMS issues with authority compromises strategic planning, advocacy, and adequate funding for out-of-hospital emergency care. Forty years after the first white paper was published, a reassessment of the future of emergency care in the US health system was undertaken by the Institute of Medicine, which offered as one of its many recommendations that a lead agency should be housed in the Department of Health and Human Services, and should have primary programmatic responsibility for the full continuum of EMS and emergency and trauma care for adults and children, including medical 9-1-1 and emergency medical dispatch (EMD), prehospital EMS (both ground and air), hospital-based emergency and trauma care, and medical-related disaster preparedness (1).

At present, the Federal Interagency Committee on EMS, supported by the National Highway Traffic Safety Administration (NHTSA), works to ensure coordination among the federal agencies involved.

EDUCATION

The Office of EMS at the NHTSA has served as the source of national standard educational curricula since the EMT-A curriculum was established in 1971. Curricula were developed for prehospital providers at the first responder, emergency medical technician-basic

(EMT-B), emergency medical technician-intermediate (EMT-I), and emergency medical technician-paramedic (EMT-P) levels of education. While these curricula were accepted as national standards, states variably adopted them, often with heavy modification for the training of EMS providers in their jurisdictions. As a result, a great variety of provider levels with differing scopes of practice emerged nationally. Although this diversity allows for the greatest flexibility to respond to local needs with local resources, it does not foster uniform scopes of practice or standards of care and creates confusion regarding interstate reciprocity of privileges. To address this issue, the NHTSA sponsored an EMS Education Task Force composed of EMS providers, administrators, educators, and physicians, which authored the "EMS Education Agenda for the Future: A Systems Approach." This document calls for more explicitly defined core educational content, scope of practice, and national standards for the education and certification of providers. The Agenda calls for an education system with five primary integrated components: (a) the National EMS Core Content, (b) the National EMS Scope of Practice Model, (c) National EMS Education Standards, (d) National EMS Education Program Accreditation, and (e) National EMS Certification. The National EMS Core Content, published in July 2005, specifies the knowledge and skills necessary for the provision of care in the out-of-hospital environment and was developed using the "Model of Clinical Practice of Emergency Medicine" as a template to facilitate common definitions and terminology with colleagues practicing emergency medicine in the hospital environment. The National EMS Scope of Practice Model, published in February 2007, defines and describes four levels of EMS licensure—Emergency Medical Responder, EMT, Advanced EMT, and Paramedic—each representing a unique body of knowledge and skill set. National EMS Education Standards are also published, that define the competencies that must be met by graduating EMS personnel to meet practice guidelines. These standards now replace the NHTSA national standard curricula at all levels of practice. This new educational model and the newly defined levels of licensure are gradually being adopted and implemented by the states.

Independent of the core curricula, there have also emerged specialized training programs, established for EMTs and paramedics who function in settings wherein additional education is desirable. Programs can be found to enhance education and training for critical care transport, wilderness medicine, law enforcement special operations and medical support among others.

The training of physicians for leadership roles in EMS continues to develop. Historically, any physician who had an interest and the fortitude would serve as an EMS medical director. No formal training existed. Today, emergency medicine residents are provided some education in EMS systems and prehospital care as part of their core curriculum in postgraduate training. Postgraduate EMS fellowship training has also been available through 1- and 2-year training programs. The 2-year programs concurrently offer a master's degree in public health, hospital administration, business, or other disciplines. In 2010, the American Board of Emergency Medicine formally accepted EMS as a certifiable subspecialty. The American College of Graduate Medical Education now provides accreditation for EMS fellowship programs in the United States that is based upon established standards and guidelines.

STRUCTURE

The structure of EMS systems varies widely across the United States, but common elements do exist: (a) activation of the system, most predominantly by use of 911, (b) medical interrogation of the call to facilitate the dispatch of appropriate responders and provision of prearrival instructions, (c) dispatch of EMS ambulance personnel and sometimes first responders to the scene, (d) treatment and transport of patients in the out-of-hospital environment, and (e) arrival of patients at a medical treatment facility and transition of care. The system design should ensure efficient and effective service and medical care, measured by desirable patient outcomes. Regionalization of EMS may yield operational efficiencies and facilitate agreement on the threshold of clinical encounters required by EMTs to maintain proficiency and skill, when compared with highly fractionated systems.

There are multiple delivery models currently in use.

Fire-Based Systems

Many fire departments (FDs), especially in the western United States, adopted EMS as part of their mission immediately after the federal legislation was enacted. Fire-based systems allowed dispatch and deployment of EMS units within a currently existing system. In most combined EMS/fire systems, EMS accounts for about three-fourths of the call load. In small cities and towns, existing personnel and facilities may be able to perform EMS duties without adding staff or infrastructure. However, because firefighters are usually among the highest-paid employees, larger systems that need additional staff will incur much higher costs as compared with the other EMS models.

In addition, because the FD's first priority is fire suppression, conflicts of interest may arise and lead to under resourced patient care. As the annual number of fire-suppression calls decreases and cities look more closely at the most efficient use of available resources, more FDs are becoming interested in EMS. Integration of established EMS systems with and under the direction of FDs is a politically charged topic that currently is the subject of heated debate in many cities.

Many FDs provide first-responder services regardless of the source of ambulance transport, using firefighter personnel trained to provide initial interventions for immediately life-threatening conditions such as cardiac arrest (CA), respiratory distress, chest pain, and loss of consciousness. In some systems, the FD may also provide the full scope of paramedic services and patient transport for every patient or alternatively for a sub-set of patients in partnership with a private ambulance provider.

Private Ambulance Services

Private ambulance services often bid for an exclusive contract with a governmental entity to provide EMS services, usually to a city, town, or county. The contract often stipulates that certain indirect measures of quality and performance be met, such as that all units be

equipped with defibrillators, that paramedics perform a minimum number of intubations, or that certain response-time parameters be met. The community establishes regulatory control over the private service, with oversight being provided by an EMS agency or a medical director.

Private ambulance services usually provide both advanced life-support (ALS) and basic life-support (BLS) services. To a greater extent than any of the other EMS models, private ambulances depend on efficient management of resources, such as peak-load staffing and system status management, to meet their dual demands: providing adequate EMS response and being a successful business. Personnel costs for the private sector are usually significantly below those for both the FD and third-service industries. The risk, however, is that the vendor could withdraw from nonlucrative markets, leaving the region or municipality searching for a means to provide uninterrupted service.

Third-Service Systems

Third service, simply defined, is an EMS system housed in a municipal department using municipality-owned and -operated ambulances and kept separate from police and fire services. Many medium and large cities continue to use municipal hospital–based ambulances as all or part of their EMS systems. Some third services are part of the city's health department, and a few are separate city agencies. This model allows for concentration on one mission—patient care—without the added complexity of managing, funding, and providing other services. EMT skill maintenance is rarely a problem in these mostly urban systems. A drawback is that the third-service agency must compete with other traditionally well-supported public service agencies for budgetary funding.

Volunteer Systems

Three-fourths of the United States is considered rural, and in these areas the EMS workforce depends largely on volunteers. The tax base cannot support a full-time professional EMS system, and the revenue

to attract a private contractor does not exist. The dedication of volunteers is remarkable, as are the challenges they face in finding medical oversight, time for training, the means to maintain their skills, and the financial resources to develop and maintain their systems' infrastructure. Depending on state regulation, some volunteer services may operate without medical direction. Turnover among these providers is high. Rural systems face the same challenge of delivery of quality care as urban ones but often with drastically different resources.

AMBULANCES

Ambulance vehicles are a very diverse fleet, including vans and light and heavy trucks, which have evolved without keeping stride with advances in the automotive and occupational safety industries. Vehicle crashes have been shown to be the number one cause of occupational mortality in EMS. Risky driving practices and noncompliance with use of seat belts contribute to high injury and fatality rates in ambulance crashes. Driver feedback technology has shown favorable results in modifying driver behavior. It has also become increasingly clear that the vehicles used for EMS operations are not optimally designed for occupant safety (2). There is increasing pressure to design ambulances that afford EMS personnel and patients maximum protection in the event of a motor vehicle collision. Cleared head strike zones, secured equipment, and appropriate restraint of patients and EMS personnel are issues that need to be addressed. Changes in driver and occupant practice and ambulance design deserve attention and will afford better protection for the occupants and greatly improve the chance of patients' and EMS personnel's surviving a traffic accident.

Federal and state laws, which can be extremely detailed, govern the configuration of each vehicle and its markings. In addition, each state mandates the minimum and allowable equipment and medications carried on any ambulance. Despite these regulations, there is wide variation of equipment and medications carried on individual ambulances. These variations reflect not only the medical director's equipment preferences, judgment, and vision for the

service but those of other personnel and the type and geographic location of the system.

Variation in equipment and supplies also reflects the level of service provided. The amount and variability of medical equipment on a BLS ambulance is typically much less than on an ALS vehicle.

MEDICAL OVERSIGHT

Medical oversight of out-of-hospital providers is essential to providing the best medical care. It may take the form of direct or indirect medical control. *Direct* or *online* medical control refers to the immediate direction and feedback, usually by radio or telephone that a physician provides to an EMS provider while caring for a patient. Although there is some controversy over whether such communication significantly improves the care provided, it gives EMS providers direct access to a physician's level of training and knowledge.

In some systems, *a specified physician or institution at a single base hospital provides online medical control.* In other systems, it is decentralized, with each receiving institution acting as a base station. Medical control physicians must have an in-depth knowledge of the skills and capabilities of the EMS provider on scene and the capabilities and availability of receiving institutions in the area. They must also know applicable state and regional or local protocols and the medico legal implications of situations such as refusal of treatment or transport and the care of minors, do-not-resuscitate patients, and deceased patients.

Indirect or *off-line* medical control consists of clinical guidance document (or protocol) development and implementation, equipment selection, ensuring adherence to clinical standards, education of EMS providers, and ongoing quality improvement within the system. Such functions are generally the responsibility of the EMS medical director. The highest-functioning EMS agencies are characterized by the triad of commitment to excellence in patient care, dedicated EMS personnel, and actively engaged medical directors. Care must be "patient-centric and physician-directed." Compliance with written clinical guidance and standards of care is usually accomplished by

reviewing EMS patient care records. This is accomplished by the EMS medical director or designee reviewing individual cases that were difficult or problematic or by reviewing the charts of selected conditions (e.g., CAs, pediatric cases, intubations, deaths, refusals of care) or individuals (e.g., new hires, those with whom there may be quality-of-care concerns, those who have just returned from a leave of absence). In addition, in a highly functional EMS agency, the medical director and other supervisory personnel must spend time "in the field" with their EMTs and paramedics. Chart review can never replace the invaluable experience of seeing how personnel function in their element. EMS agencies must be committed to continuously evaluating the quality of the service delivered and striving to seek ways to improve it.

The initial training and continuing education of EMS providers is a key element in medical direction. The implementation of new medications, interventions, and protocols is an ongoing process. Quality improvement includes not only identifying and correcting deficiencies in current practice but identifying areas that, although not necessarily deficient, can be improved (response time, scene time, timely completion of charts, documentation of procedures).

COMMUNICATION

EMS communication is a chain of events that can be best described using queuing theory. The call-taker queue consists of those who dial 911. In the past, most cities and towns had their own emergency call-receiving center, but with the advent of *Enhanced 911* (911E), many have now been consolidated into Public Safety Answering Points (PSAPs) serving one large local jurisdiction or multiple smaller ones. 911E provides the PSAP call taker with the physical address of the phone (street address and, in apartment buildings, the apartment number) and the telephone number of the caller. In most jurisdictions, once the last digit of 911 is dialed, the caller cannot disconnect by hanging up. Only the public safety dispatcher can release the 911 call. This prevents the panicked caller from disconnecting the call before all information is obtained and prearrival instructions are offered. The demographic information

allows patients who are unable to speak as a result of illness, injury, or danger to receive assistance. Protocols may also allow the call taker to ask a series of yes or no questions that mute callers can answer by pushing the appropriate button (1 or 2). In this way, the correct agency or agencies can respond. Technology is also available to approximate the location of cell phones within a few dozen meters, a feature useful for the location of automobile accidents and one that enables the direct routing of a 911 call to the appropriate PSAP. In 2006, approximately 59% of PSAPs had this capability, compared with 18% just 3 years prior (3).

EMS callers are then placed in the triage queue. Modern EMS systems use written telephone medical triage guidelines, known generically as EMD, to ensure consistent and appropriate triage and response. More important, by asking only for information that will assist in correctly prioritizing the call, they reduce the amount of time spent questioning the patient prior to dispatch. For example, if the caller is male, older than 50 years of age, and has nontraumatic chest pain, no further information is necessary for triaging the call as high priority (potential cardiac etiology). Gathering additional information and attempting to make a presumptive diagnosis is not appropriate and possibly detrimental, because it wastes time and is not relevant to the dispatch decision.

Triage protocols can reduce both type 1 and type 2 errors (over- and undertriage). They also protect the call taker from the abusive retrospective review that can occur after a high-profile adverse event. Because the medical director bears responsibility for the appropriateness of these medical triage guidelines, it is strongly suggested that a nationally recognized EMD product be used. Some of these products are customizable (within limits) to meet local preferences, whereas others require use “as is.”

EMS calls are usually triaged into one of three priorities: *Priority One:* life-threatening; *Priority Two:* emergent or unknown; and *Priority Three:* nonemergent. These categories are designed to reflect the instability of an illness or injury and its likelihood of deteriorating in a short period of time. They are not intended to characterize whether the condition justifies the use of an ambulance

or how serious it is. For instance, although a fractured hip is serious and appropriate for the use of an ambulance, it is not likely to deteriorate and, therefore, does not have top priority.

Once the call is prioritized, it enters the dispatch queue. The dispatcher then assigns an ambulance to respond. Assigning the closest ambulance to the call is preferred, but this process is not always straightforward. As the number of ambulances in a system increases, so does the complexity of dispatch. In larger cities, the dispatcher would have to know each street and the location of each ambulance at any given time. Most ambulances are available to be dispatched, or "in-service" 60% to 85% of the time, and they may be located outside their assigned districts, making it difficult to ascertain their position without polling multiple units over the radio.

Automatic vehicle locator (AVL) systems can help and are increasingly being used, particularly within the private sector. Using the federal government global positioning satellite system, AVLs can locate an ambulance within a few feet, calculate the travel time to a given call, and recommend the nearest units of each appropriate type —first-responder, BLS, and ALS.

EMS demand by time of day is remarkably predictable, especially in systems with a large call volume. System status management is the process of managing resources based on known patterns of calls in time and place and current demand. Additional ambulances are placed in service during known periods of higher demand. Available units do not remain static but are dynamically and proactively redeployed by EMS supervisors when call volume is high in certain areas. The practice of flat staffing, in which the same number of ambulances are on duty 24 hours a day, is less efficient; patients will have to wait longer than necessary during the busier times, and resources will be wasted during slack time.

DISASTER PLANNING

Mass casualty incidents (MCIs) require the response of multiple different public safety and EMS agencies. They threaten to overwhelm the capacity of the out-of-hospital care system and the medical facilities supporting them. Each EMS agency and hospital

must have a plan for dealing with MCIs in their service area. The importance of having a well-understood, rehearsed, and commonly recognized plan for responding to an MCI cannot be overemphasized. Practicing implementation of the plan provides training for all participants, prevents needless delays, and identifies areas for improvement. Agencies should have complementary plans and train together to ensure cooperation. Planning and training must take into consideration challenges identified in previous responses, which include self-dispatch of responding units causing congestion at the scene; overload of the hospitals in the immediate vicinity of the event; self-evacuation of patients from the scene to the nearest emergency department (ED) prior to EMS evaluation; and the least severe patients often arriving first in the ED (4).

Risk assessment of potential MCI scenarios in a service area is essential. It involves recognizing and characterizing likely sites of an MCI, such as industrial complexes, airports, residential areas (e.g., high-rise apartments, special-needs facilities), highways and railways, and unique facilities, such as nuclear power plants.

A mechanism for rapidly triaging victims of an MCI should be identified and rehearsed. The objective of patient triage is to do the greatest good for the greatest number of victims. Given that several triage criteria have been published and disasters often cross jurisdictional boundaries, the Model Uniform Core Criteria for Mass Casualty Triage (5) was developed to serve as a national guideline for mass casualty triage with the goal of facilitating interoperability and standardization. The criteria include four categories: (1) general considerations, (2) global sorting, (3) lifesaving interventions, and (4) individual assessment of triage category. The SALT (Sort-Assess-Lifesaving Interventions-Triage/Treat) triage system is freely available and meets the Core Criteria (Fig. 376.1). Patients are ultimately assigned to severity categories with the goal of identifying those who require treatment and transport to a medical treatment facility most urgently. Patients are assigned to one of five categories: immediate (red), delayed (yellow), minimal (green), expectant (gray), or dead (black). *Immediate* patients are critically wounded with obvious life-threatening injuries and will require immediate

care. *Delayed* patients have a serious injury but will likely not deteriorate with a slight delay in care. *Minimal* patients do not have life-threatening injury and will likely do well even if care is withheld several hours or days. *Expectant* (gray) and *dead* (black) victims have injuries consistent with little or no chance for survival or have already expired. It is important to note that patients may be triaged several times on their way to definitive care to account for changes in their condition.

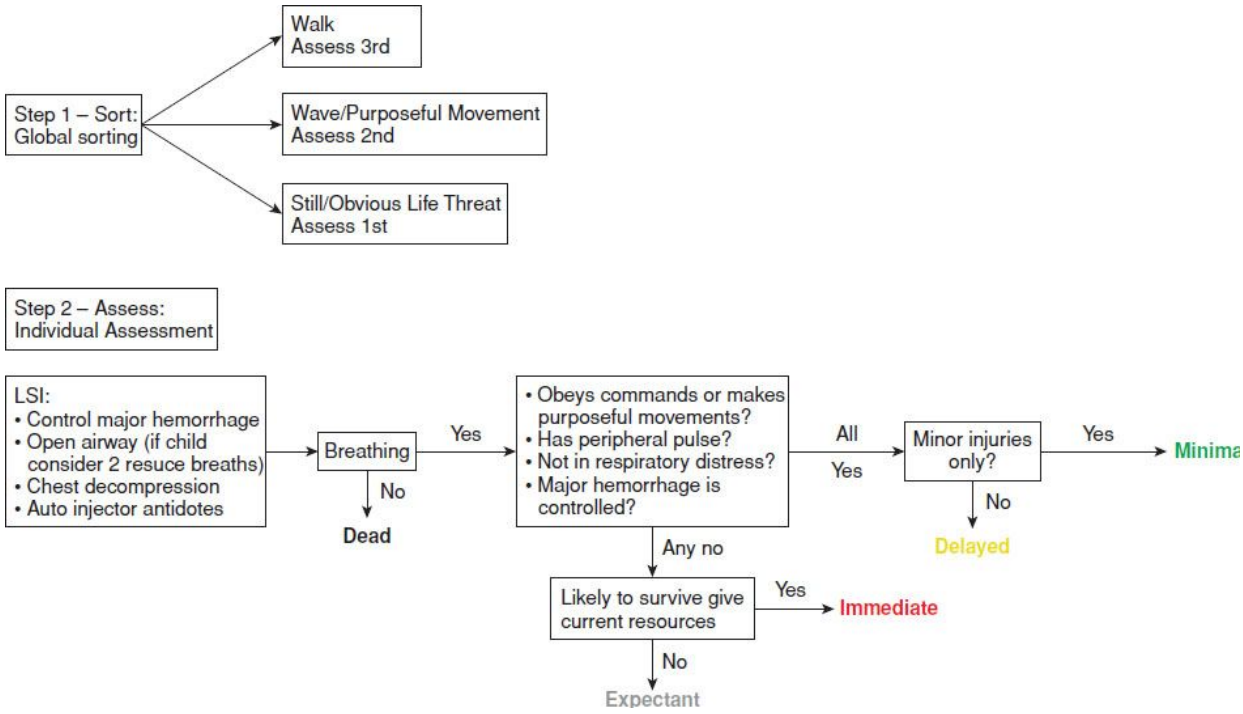

FIGURE 376.1 SALT mass casualty triage (in the public domain).

A communication plan is essential. Often, however, it is the part of the response that fails most rapidly in an MCI. Overloaded radio channels, cell channels, and phone lines can be expected. Loss of radio towers and telephone wires may occur. The plan should identify ways to minimize the effect of these occurrences.

Mutual aid agreements with EMS, police, and fire services and medical treatment facilities in contiguous service areas should be in place. The ability to assemble out-of-hospital and hospital assets beyond the affected area is often essential for a timely response to an

MCI. The plan should identify the resources, personnel, transport, equipment, and facilities that can be called upon.

A clearly defined incident command structure should also be in place. In some states, the highest-ranking fire officer serves as overall "incident commander," with police, EMS, and other agencies functioning as subcommands under incident command rules. All involved must use common nomenclature, practice, and communications protocols. There should be clear direction regarding what freedom of operation prehospital providers might have without resorting to frequent online medical direction. Freedom of operation can be accomplished by having the medical director or designee assume medical command at the scene or via radio.

Special planning is required for HAZMAT situations, terrorist activities, weapons of mass destruction, and mass gatherings. Finally, a debriefing plan is necessary to allow for psychological recovery of involved personnel and for the planning to manage future MCIs.

Mass gathering medicine, defined as organized emergency care for mass gathering events, has evolved and become more sophisticated in the last 30 years. The concentration of many people in a small geographic space can pose significant challenges to proper prehospital management of patients. Recognition of a medical emergency may be difficult, and access to the patient may be hindered, delaying care. An MCI might quickly develop, and on-site resources can quickly be overwhelmed. Agreement with the event organizer about what medical resources are required to provide adequate emergency services may be difficult. Demands for medical care are often not defined by crowd size alone. Exposure to adverse weather conditions, spectator use of alcohol, inadequate intake of water, consumption of contaminated food, and violent spectator behavior can all increase the likelihood of injury and requirement for medical attention. Rock concerts (0.96 to 17 injuries per 1,000 fans) have, for example, had a higher incidence or injury than major sporting events (0.3 to 1.6 injuries per 1,000 fans) (6). The threat of terrorism has also influenced the development of mass gathering medicine. On a national level, an event may be deemed a national security special event because it is high profile and identified as a

possible target of terrorism. In addition to enhanced security measures coordinated by the US Secret Service, medical assets, in the form of disaster medical assistance teams may be deployed to assist local responders in the event of an MCI. The Olympics, major political conventions, and the World Economic Forum are examples of such events.

FINANCING EMS SYSTEMS

The expense of an EMS system is a function of personnel, administration, maintenance, training, equipment, and facilities. Other variables include the level of service provided, response-time requirements, how the cost will be apportioned among patient revenues, tax revenues, and other subsidies, the insurance coverage of the population served, and the cost of medical oversight.

Funding of EMS systems varies greatly from system to system but can be divided into four major categories: taxes, fee-for-service billing, subscription program revenues, and special service contracts. Local and state tax subsidies can entirely fund an EMS system in which care is provided as a public service. Most often, this funding comes from general tax revenues and must compete with other public programs for scarce tax dollars.

In some states, the law allows citizens to approve a dedicated tax levy for specific purposes, and voters direct funding for EMS services. Because EMS has a very positive public image, EMS systems tend to enjoy a greater degree of financial support under such a system. In other systems, tax subsidies may simply offset costs that cannot be covered by revenues from EMS billing. Subsidies are often required in small communities that lack economies of scale, yet operate a full-service EMS system, and in urban and rural settings. It may flow through the budget of a government agency, in the case of third service or FD, or it may be a contractual agreement between a private ambulance provider and a local government. With private contracts, most cities and towns have enjoyed almost a decade of subsidy-free EMS services, as providers have received sufficient revenue from Medicare and Medicaid reimbursement. Diminishing reimbursement from these sources has significantly reduced the

ability of private ambulances to continue subsidy-free 911 contracts. Systems serving communities with a large number of uninsured indigent patients are particularly in need of funding sources to offset costs that cannot be covered by revenues.

In a service that generates its revenue from a fee-for-service plan, income is derived from emergency and nonemergency patient transports, interfacility transfers, and special-event coverage. To balance the budget, these systems must have adequate economies of scale, a population base that has the means to pay, efficient management, and effective billing. Among the billed entities are Medicare, Medicaid, private insurance companies, and individual patients.

Subscription programs are marketed to the populace by a vendor who essentially enrolls people as an "insurance policy" in case they need ambulance services. This type of system also provides service to unenrolled members but at a charge significantly greater than the enrollment fee. Some arrangements also allow the company to bill third-party payers. Special-events coverage, interfacility transport, air transport, and other contracts can provide added revenue.

EMS FOR CHILDREN

Perhaps no group of patients inspires more angst among EMS providers (and emergency medicine personnel) than ill and injured children. Although they make up only a very small percentage of EMS patient interactions, they are among the most difficult to manage. Children younger than the age of 18 make up approximately 13% of all EMS transports (3). Half of these calls are for a traumatic condition, with falls and vehicular trauma being the leading causes of injury. Respiratory difficulty, seizures, ingestions, drowning and near-drowning, fever, and altered mental status are common chief complaints. Sick children generate tremendous feelings in the medical professionals who treat them. Being able to simultaneously deal with the needs of the critically ill or injured child and the provider's own emotions (especially if they have children of their own) is a serious challenge to the provider's professionalism. Almost all EMS personnel can relate to a

particularly ill or injured child who affected them on a visceral level during their careers. Finally, children are different from adults. Their anatomy, physiology, and responses to interventions differ from those of adults. Thus, when dealing with sick children, EMS providers are treating a group they rarely see, who will affect them emotionally, and are different from the vast majority of patients they encounter on a daily basis.

Emergency medical services for children (EMSC) is a federal, state, and local effort to ensure that all children have the same access to high-quality EMS care as do adults. Starting in the 1980s, with federal legislation providing for grant programs based in the US Department of Health and Human Services, EMSC has funded databases, provided grants to the states to study and address the issues experienced by ill or injured children, and convened expert panels to enhance the care delivered to children in the out-of-hospital setting.

A key portion of the EMSC initiative is improved education of EMS providers on the special needs and requirements of ill and injured children. Traditionally, EMS providers had little to no experience or training in treating children. EMTs and paramedics would typically receive 1% to 2% of their total training time on the unique aspects of treating pediatric patients. This has been changing. Paramedic training now includes the Pediatric Advanced Life Support course and the new Pediatric Education for Prehospital Providers course. In addition, many state EMS protocols have specific pediatric protocols, written by emergency physicians and pediatric emergency medicine specialists to guide prehospital providers in treating children. Innovative programs, such as having paramedics spend time in pediatricians' offices, are increasing the comfort levels of both the prehospital providers and the pediatric community. Physicians who provide both online and off-line medical direction are assisting in these developments and are now active participants in furthering the care of pediatric patients.

Special Challenges in Treating Pediatric Patients

Prehospital personnel are faced with a unique set of demands and must use a different set of knowledge and skills when dealing with pediatric patients. As examples, children have a relatively larger occiput than adults, requiring that their torsos be elevated to the level of the occiput to achieve an anatomically neutral position during spinal immobilization. Airway anatomy is different and physiologically, children have higher metabolic rates, requiring higher oxygen demand per unit body mass. The EMT or paramedic with little pediatric experience may fail to accommodate these differences with subsequent clinical deterioration of the child.

Peer-reviewed literature has challenged the "basic" tenets of treating the injured or ill child. One study questions the benefits of prehospital intubation over noninvasive airway management (7). No difference was demonstrated in the outcome of children managed with an endotracheal tube versus conventional bag-valve-mask ventilation. The study, however, was criticized for having an extremely low rate of success for paramedic field intubations in children and frequent complications of airway management, such as unrecognized esophageal intubations. Medical directors evaluating this study may conclude it better to noninvasively manage pediatric airways. Conversely, EMS medical directors may opt for more robust training and oversight of their system's pediatric intubation program. A recent review of a statewide EMS database revealed >67% ALS providers performed two or fewer endotracheal intubations per year, and >39% did not perform any (8). Another study evaluated pediatric medication dosing errors in children treated by EMS. During the study period 4% of the children were administered drugs and had a documented weight. Weight-based medication dosing errors occurred in 35% of drug administrations (9). Paramedic encounters with pediatric patients are infrequent. Alone they are unlikely to ensure clinical acumen and skill proficiency. Robust EMS educational initiatives are needed to address the maintenance of pediatric skills in prehospital providers.

EMS AND TRAUMA

The “modern era” of EMS in this country was ushered in as a response to traumatic injury and death on America’s highways. Trauma was the catalyst for the drafting of the white paper (“Accidental Death and Disability: The Neglected Disease of Modern Society”) that prompted improvement of essential prehospital infrastructure, training of personnel, and establishment of practice guidelines. In the 50 years since the drafting of the white paper, three basic tenets of trauma patient management in the prehospital setting have clearly evolved. They include (a) rapid response to the patient, (b) effective management of ventilation, oxygenation, perfusion, and immobilization, and (c) rapid transport to the most appropriate facility.

Rapid response to the patient is determined by multiple factors including recognition of the event, access to the 911 system, the efficiency of the communications center, and the proximity of units available to respond to the scene.

Effective management of ventilation, oxygenation, and perfusion is determined by the quality of the education provided for the responding EMS personnel and the quality of medical oversight enjoyed by the service. Quality adjuncts to the core curriculum of training exist in programs such as Prehospital Trauma Life Support and Basic Trauma Life Support. These programs champion principles of prehospital trauma care, such as scene safety, rapid primary survey, airway control, adequate oxygen delivery and ventilation, control of hemorrhage, management of shock, immobilization, and transport.

Rapid transport of the patient to an appropriate facility is determined by EMS education and medical oversight but can also be facilitated by regional trauma systems. EMS education and oversight are critical for limiting the scene time, focusing on those interventions that are thought to be life saving in the first few minutes of the EMS response and not wasting precious time on interventions that could be performed en route to or in the hospital. The goal is to preserve as much as possible the “golden hour” after the injury until arrival at the appropriate medical treatment facility. Regional trauma systems facilitate this tenet of prehospital care by

identifying the appropriate trauma centers in a region and establishing guidelines for patient transport to these facilities. Guidelines are published for field triage of trauma patients (Fig. 376.2) (10). Air medical transport systems also play a role in regional trauma systems and assist in ensuring the rapid transport of injured patients to appropriate medical facilities. Guidelines for the use of air transport are promulgated by the National Association of EMS Physicians and the Air Medical Physicians Association (11).

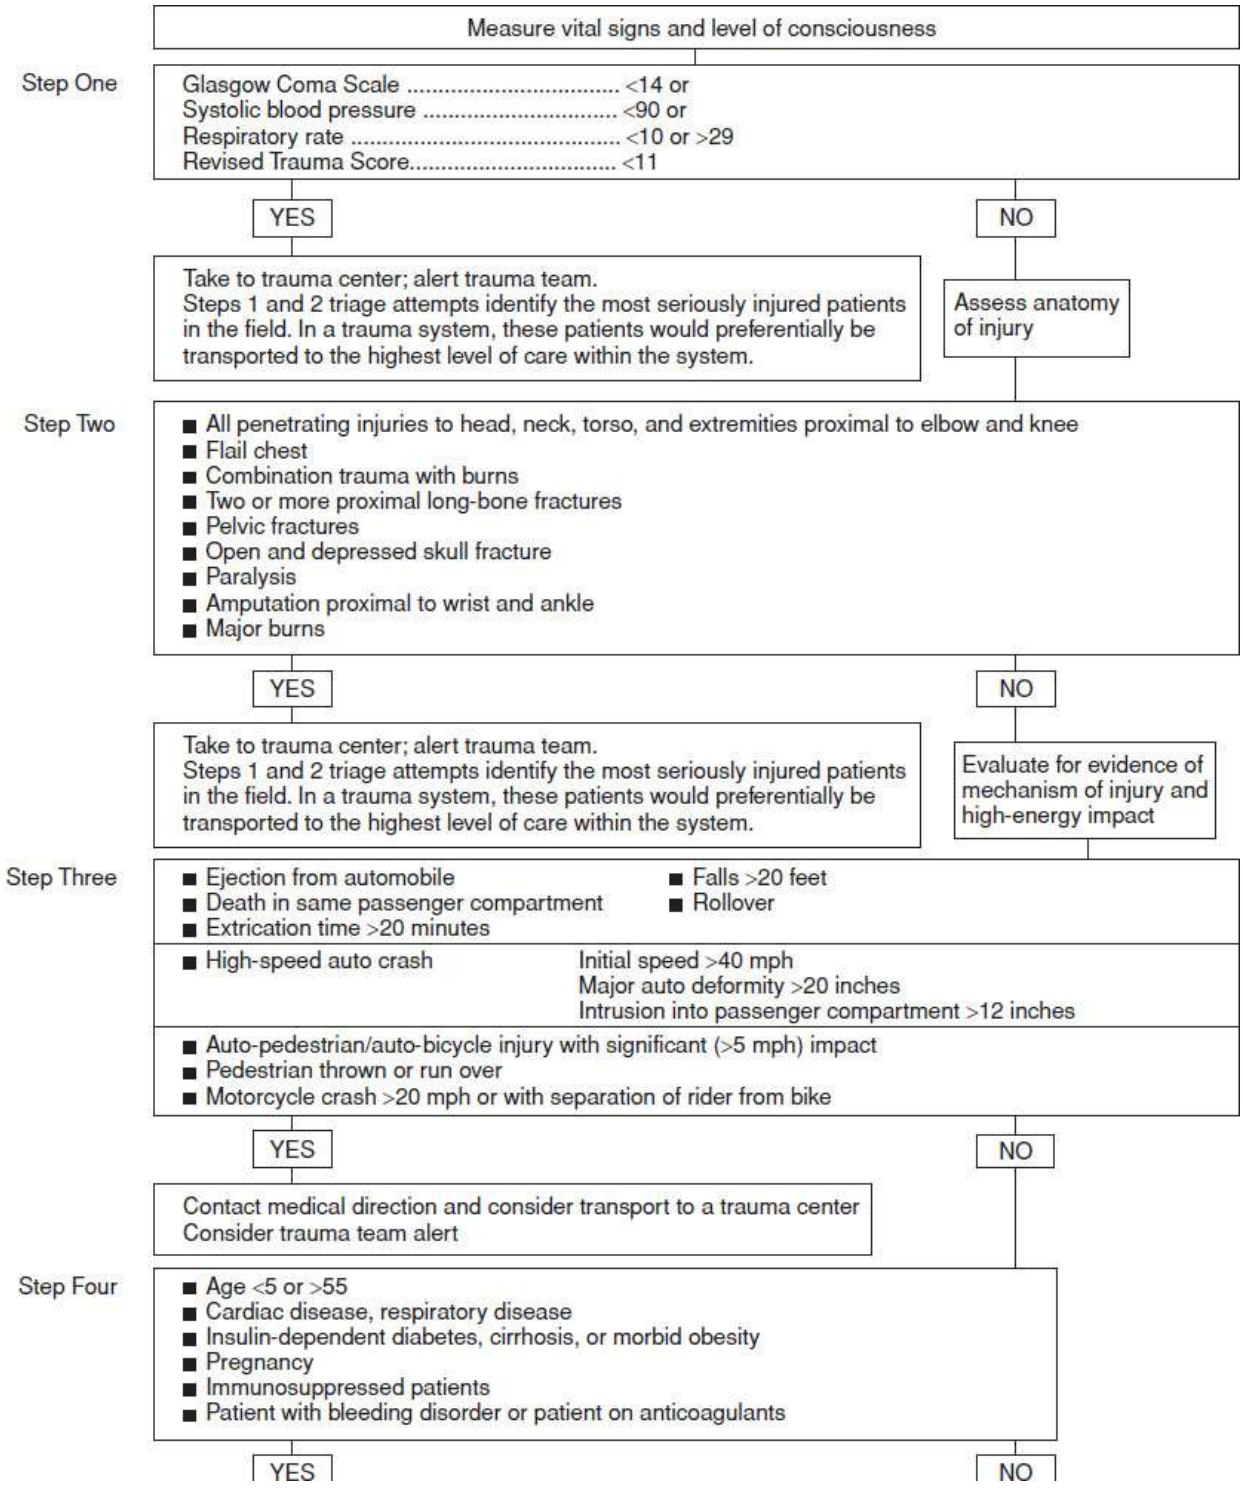

FIGURE 376.2 2011 Guidelines for field triage of injured patients (in the public domain and available at http://www.cdc.gov/fieldtriage/pdf/decisionscheme_poster_a.pdf).

The NHTSA and many other stakeholders in the management of trauma patients have drafted the Trauma System Agenda for the Future. Prehospital care is identified as a fundamental component of the trauma care system, along with injury prevention, acute care hospitals, and posthospital care. Challenges to quality prehospital care of trauma patients include isolation of EMS from the injury prevention and acute care hospital components of care, inadequacies of the national 911 system, inequities in distribution of EMS resources, prolonged transport times from rural communities, over- and undertriage of patients to trauma centers, and ED overcrowding and diversion. Visions for the future include (a) better integration of EMS into injury prevention initiatives and improved dialogue with treatment facilities, (b) standardized protocols and triage, (c) strategic placement of transport vehicles to improve access in rural, underserved communities, and (d) improved communications, including automated collision notification, universal 911 coverage, and enhanced communication with prehospital providers facilitating more accurate triage and delivery of care.

There is a need for prospective randomized controlled clinical trials to resolve the many controversies regarding medical interventions in the prehospital care of the trauma patient. Research can challenge the very basic tenets of patient management in the out-of-hospital setting.

Because of the risk of aspiration and increased mortality associated with hypoxemia in patients with traumatic brain injury (TBI), endotracheal intubation has become a goal of prehospital management. It was then somewhat surprising when, in a recent study, paramedic rapid-sequence intubation protocols, which have been shown to increase the intubation success rate, were associated with an increase in mortality in head-injured patients (12). Another study showed that when compared with ED endotracheal intubation, prehospital intubation of TBI patients was associated with nearly a fourfold increase in mortality (13). These studies and others have led to a careful examination of inadvertent hyperventilation and the increased mortality associated with severe hypocarbia in TBI patients intubated in the field (14). Research of clinical care provided in the

prehospital environment is critical for evaluation of interventions and their contribution to patient outcome.

Management of casualties on the battlefield is informing the control of external hemorrhage. Demonstrated efficacy of the prehospital application of tourniquets with minimal associated complications, when ischemic times are limited, has led to adoption of their use in the civilian environment for control of rapid extremity exsanguination. The use of hemostatic agents in the prehospital setting is also being adopted (15).

Longboards used for spinal immobilization are increasingly recognized as contributors to pain, patient agitation, and respiratory compromise. More judicious backboard use and setting appropriate alternatives are being encouraged (16).

RESEARCH AND INITIATIVES FOR THE FUTURE

Proper prehospital provision of care requires research that explores both system design and clinical interventions. Much of the delivery of prehospital care is not supported by research that demonstrates improved patient outcome. The NHTSA and its partners address the science of prehospital care in its National EMS Research Agenda. It identifies five major impediments to the performance of high-quality research: (a) a paucity of highly skilled researchers, (b) inadequate funding, (c) failure of EMS professionals to acknowledge the importance of EMS research and its transition into practice, (d) lack of data integration that promotes study of patient outcomes, and (e) difficulty in obtaining informed consent in the prehospital environment. The Agenda offers a strategy to overcome these obstacles.

Despite these obstacles to evidence-based care, several good studies have been published that better inform the design of EMS systems and delivery of out-of-hospital care.

The Ontario Prehospital Advanced Life Support (OPALS) Study is a large prehospital study that involved more than 25,000 CA patients with the intention of evaluating the incremental benefit of rapid defibrillation and prehospital ALS measures for CA survival (17). Phase I of this trial reported the baseline survival status after

introduction of an automatic external defibrillation (AED) program in an area in which no AED or ALS services were present (18). Improved survival from CA was associated with younger age and a witnessed event. The authors identified three other areas that are amenable to EMS system optimization: (a) survival may be improved by minimizing EMS response intervals; (b) survival is improved threefold if CPR is initiated by a bystander; and (c) survival doubled if initiated by fire or police first responders. Phase II of the trial verified that procedures that reduced the time to defibrillation significantly improved the survival to hospital discharge rate. An improvement from 72% to 93% for calls responded to within 8 minutes or less by the AED crew resulted in a 33% relative increase in the survival rate (19). Phase III of this study evaluated introduction of ALS interventions (endotracheal intubation, intravenous drug therapy) for the management of out-of-hospital CA in a previously optimized rapid defibrillation program (20). This trial did not identify any incremental mortality benefit associated with ALS interventions in this setting, though intermediate survival outcomes, such as return of spontaneous circulation and admission to hospital, did improve. It did also confirm the association of early access, early CPR, and early defibrillation with improved mortality. The OPALS study also evaluated a specific regimen of ALS interventions for the management of acute respiratory distress (congestive heart failure, pneumonia, chronic obstructive pulmonary disease, and asthma). The study showed a significant decrease in mortality from 14.3% to 12.4% when ALS interventions were introduced (21).

The study of out-of-hospital CA survival is one important benchmark for the evaluation of EMS system effectiveness. The Cardiac Arrest Registry to Enhance Survival (CARES) collects standardized, confidential, out-of-hospital CA survival data and shares it with the local EMS providers and communities, giving them the opportunity to evaluate, benchmark, and improve their survival rate from sudden cardiac death (22).

EMS faces significant challenges. A dated but still accurate assessment of state systems found a lack of (a) comprehensive EMS

legislation and statewide EMS plans, (b) enhanced communication systems, (c) consistent quality-assurance programs for training courses and instructors, (d) enabling legislation for trauma system development, (e) consistent and adequate funding sources, (f) priority for public information and education programs, and (g) effective data collection and evaluation systems (23). The EMS Agenda for the Future is a blueprint with recommendations for improvement of 14 EMS attributes: (a) integration of prehospital care with public health, injury prevention, and acute care, (b) EMS research, (c) legislation and regulation that will fund essential federal and state initiatives, (d) system finance to ensure proper EMS infrastructure development, (e) human resources to provide a viable career path for prehospital care providers, (f) medical direction with appropriate credentials and sufficient resources, (g) education systems for the development of quality prehospital providers, (h) public education to better inform the community on EMS utilization, (i) injury prevention, (j) public access, (k) EMS communications, (l) prehospital clinical care, (m) information systems, and (n) evaluation of service regarding medical outcomes and cost effectiveness (24). Through its unique position in the community as a link to healthcare access, the "scope of service" of EMS systems may expand to encompass injury prevention and preventive medicine initiatives, complementing and enhancing roles currently served separately and independently by other agencies.

Common Pitfalls

- Introduction of prehospital medical interventions without adequate investigation regarding improvement in patient outcome.
- Failure to insist on engaged medical direction in the delivery of prehospital medical care.
- Failure to have a well-understood, rehearsed, and commonly recognized plan for responding to an MCI.
- Failure to provide an effective plan for communication during an MCI.

- Failure to adequately plan for HAZMAT situations, terrorist activities, and mass gatherings.
- Failure to educate EMS providers on the special needs and management of ill and injured children.

CHAPTER 377

Air Medical Services

Theodore R. Delbridge

Air medical services provide transportation by rotor or fixed-wing aircraft while delivering sophisticated medical care. Optimally, they are well integrated with regional emergency medical services (EMS) and the entire emergency healthcare system. Emergency physicians should be aware of local air medical service resources, potential advantages and disadvantages of their utilization, flight physiology that may affect patients, and limitations of caring for patients in an aircraft.

HISTORICAL PERSPECTIVE

Currently, there are more than 260 air medical services deploying more than 900 helicopters throughout the United States. From 2003 to 2012, the number of helicopters being used as air ambulances increased each year (1). More than 100 services utilize fixed-wing aircraft for longer-distance transports. Approximately 30% of helicopter medical missions involve response directly to an injury or illness scene. The remainder of air medical cases involves the spectrum of seriously ill and injured patients requiring transfer from one medical facility to another.

The genesis of air medical transport can be linked to military conflict. During the Korean Conflict, mortality among wounded US soldiers was less than during World War II. At least part of that reduction was attributed to faster access to surgical care as a result of helicopter use. Helicopters were tools to overcome rough terrain and poor roads that ground vehicles would have to use. However,

no care was provided during transport, as patients were secured to litters outside the aircraft cockpit. By the Vietnam War, both helicopters and medical care had become more sophisticated. Wounded soldiers evacuated from the field were now transferred inside a helicopter, and emergency medical care commenced or was continued in flight. Air evacuation of wounded soldiers contributed to lowering the mortality rate to less than 1 per 100 casualties. The average time to reach definitive surgical care decreased from 6 to 12 hours during World War II, to 2 to 4 hours during the Korean Conflict, to 35 minutes during the Vietnam War. Currently, well-coordinated rotor and fixed-wing transport systems can get wounded soldiers to specialized definitive surgical care on a different continent within 12 to 18 hours of sustaining a serious injury.

During 1966 and 1967, army helicopters evacuated 40 civilian patients in Alabama and Texas. Between 1967 and 1970, government-funded projects verified the utility of helicopters for civilian air medical missions. They confirmed that helicopters could evacuate rural patients, make safe landings in metropolitan areas, and save valuable time. The Military Assistance to Safety and Traffic program, initiated in 1970, resulted in average time savings of 53 minutes, when compared to ground ambulances (2).

In 1970, the Maryland State Police also established its medevac program as part of a statewide EMS system. Placing helicopter bases throughout the state resulted in shorter response times to scenes and referring hospitals. The first civilian hospital-based medical helicopter program began operation at St. Anthony Hospital Systems in Denver, CO in October 1972.

Many of the same issues that affected earlier air medical programs are still germane. These include maintenance of complex and expensive communications systems. Such systems must provide reliable means of receiving requests for service from various sorts of callers, dispatching helicopters, following the progress of ongoing flights, transmitting and receiving clinical information, and facilitating online medical direction. Advances in technology have improved the reliability of effective communications across large

areas. At the same time expectations have expanded regarding the types and amount of data that are conveyed, including aircraft systems, crew, and patient clinical information.

Preparation and monitoring of the air medical crew is an obvious concern. As the sophistication of medical care has increased, so has the complexity of patients being transported. Thus, air medical crews must be more familiar than ever with an always expanding potential of therapies and interventions that they might be called on to initiate or continue as part of safely moving a critically ill patient to definitive care. Monitoring performance is a clear priority and often a challenge as a result of the relative isolation in which care is delivered. Finally, air medical services have struggled and will continue to struggle with fiscal reality. The balance between the desire to provide service and the associated costs and ability to generate revenue can be delicate. Part of the struggle entails concerns for appropriate utilization.

Nevertheless, the priorities that initially stimulated development of air medical services still remain. Mortality from trauma is higher in rural areas where transit times to trauma centers are typically longer. Approximately 28% of the US population is within an hour of a level I or II trauma center only if there is a helicopter available in their region (3). A disproportionate number of motor vehicle–related deaths occur on rural roads and highways, emphasizing the need for an EMS transportation system that is capable of expeditiously moving patients to regional trauma centers. Furthermore, regionalization of systems to care for patients with stroke, acute myocardial infarction, and serious pediatric problems has relied on air transport to appropriately distribute patients to designated centers for the care they need (4,5).

ADVANTAGES OF AIR MEDICAL SERVICES

Air medical services offer two principal advantages over ground ambulances: speed and the ability to overcome geography. When used appropriately, these advantages can result in significant savings of time to reach a trauma center or other tertiary care

facility. In the case of trauma patients, there is an understanding that the sooner the patient arrives at the trauma center, the lower the morbidity and mortality. Reducing the time to receive definitive therapeutic interventions is also important for other conditions, including stroke and acute myocardial infarction. For critically ill patients being moved between hospitals, the speed of a helicopter or a fixed-wing aircraft may result in less time outside the more controlled environment of an emergency department (ED) or intensive care unit (ICU). This can be an important consideration when precipitous deterioration is potential or when complicated therapies are difficult to maintain in transit.

To fully benefit from the potential time savings of air medical transport, it is necessary to consider all of the related events that consume time. An aircraft might provide the fastest means to get a patient to his or her destination hospital, but a number of things must occur before the patient is actually on the way. Once dispatched, helicopter liftoff typically takes several minutes, and there is no established standard. Part of that time is consumed by the pilot who must make an assessment of all the factors, such as weather, that might affect the safety of the proposed mission. For the majority of air medical services the pilot's judgment then requires validation by an aviation dispatcher at an operations center in a different location. Response time to the scene must be considered, and landing might take an additional 3 to 5 minutes. Generally, the more familiar the helicopter crew is with the landing zone and the better prepared it is, the shorter the landing time will be. Established helipads provide for the fastest and safest approaches and landings. In many cases, as a result of the difficulties in caring for patients in an aircraft, additional patient preparation must occur before initiating transport.

When considering potential time savings of air medical transport, one must weigh the total interval from the time of the request for a helicopter or fixed-wing aircraft to patient arrival at the receiving facility. It is this time that should be compared to ground ambulance transportation. In general, to optimize time-saving effects of air

medical services, they should be requested as soon as there is sufficient information to indicate their need.

Medical helicopters often are based at or near the hospital to which patients will be transported. In those cases, the response time to an injury scene or to a referring hospital is the same as the transport time. However, when air medical resources are dispersed, so that helicopter bases are remote from the receiving hospital, response times to the referring scene or hospital may be shorter, and the time savings of air medical service utilization may be enhanced. Medical helicopters typically offer little advantage in urban areas or when transport distances are short. When the transport distance is longer than 25 miles and the medical helicopter is readily available, time savings are more likely. Time savings may result for shorter transport distances if the helicopter is dispatched before the patient is ready to go, such as in cases of prolonged extrication at crash sites or when stabilizing measures are ongoing in an ED. In these circumstances, the response time of the helicopter becomes negligible.

Two pitfalls of air medical service utilization are common. The first is not summoning the service immediately when the potential need is identified. Ideally, the patient would be ready for transport and the air medical service would be ready to receive the patient at the same time. Delays in requesting or dispatching a medical helicopter can result in a patient who is then waiting for the helicopter to arrive. The second is not accounting for all the time-consuming steps required to get a medical helicopter or fixed-wing aircraft to the patient. It is not unheard of that two patients are transported from the same motor vehicle crash. One goes by ground and the other by helicopter, and the one by ground arrives at the trauma center first. While the helicopter traveled faster, all the other required steps actually made it a slower means of achieving the primary objective.

There are cases when speed is not the primary factor in choosing to utilize an air medical service. An additional potential benefit is the availability of higher levels of care during transport. Air medical service crew configurations typically consist of two clinicians

including paramedics, nurses, respiratory therapists, and physicians. The crew configuration is the result of local preference and, in some cases, state regulations. In some systems, the crew may be modified for special clinical circumstances. The result is often an air medical crew that is able to manage ongoing or potential problems better than available ground ambulance resources. Thus, the clinical expertise of the transport team and its ability to move a patient safely in an environment that is less controlled than an ED or ICU may be the major indications for air medical service utilization.

DISADVANTAGES OF AIR MEDICAL SERVICES

The three principal disadvantages associated with air medical services are complex logistics, safety, and cost. These disadvantages are appropriate to consider each time an air medical mission is contemplated.

Logistically, getting a helicopter or fixed-wing aircraft to a scene or referring hospital can be complicated. After realizing the need for an air medical service, the first step is notifying a communications center. Calls may arrive at the center from many sources including hospitals, medical control facilities, EMS agencies, law enforcement agencies, fire departments, and other communications centers. The goal then becomes to determine the location, identify the closest available helicopter, and assess whether the mission can be completed safely.

The communications center must coordinate closely with the pilot, who should remain unaware of the clinical situation to avoid biased decision making. The pilot must assess suitability of the weather and the aircraft for the proposed mission. In addition to the air medical service's communications center, separate operations centers may monitor pilot decisions. These operations centers are specific to the aviation contractors who provide pilots, mechanics, and other resources to air medical services. For each proposed mission they verify weather conditions, the mechanical readiness of the aircraft, and the qualifications of the pilot, helping to ensure that pilots are making good preflight decisions.

The incident location must be translated into information that can be used for navigation, such as latitude and longitude that can be programmed into a global positioning system (GPS). Throughout the mission, the communications center should be in continual contact with the helicopter to track its progress, convey vital patient information to the medical crew, facilitate updates to the air medical crew from ground-based medical providers (and vice versa), and implement contingency plans when necessary. Contingency plans may be necessary in cases of mechanical failure, change in weather, or change in patient condition. While en route, the helicopter crew should be able to communicate with the ground team to receive updated patient-related information when appropriate and ensure adequate preparation for a safe landing zone.

Requesting a medical helicopter to transport a patient significantly increases the workload for on-scene EMS and public safety workers and for hospital personnel when the response is to a hospital. Resources at the scene or referring hospital must be sufficient to coordinate the helicopter's arrival without distracting medical personnel from delivering care.

Safety issues should always be at the forefront. Although many safety-motivated procedural improvements have been made over the past three decades, medical helicopter operations remain inherently more dangerous than other routine helicopter operations. The safety record of air medical services has fluctuated. From 2001 to 2010 there were 132 medical helicopter accidents, defined as events resulting in aircraft damage or injury. Of these, 34% resulted in at least one fatality (6). Year-to-year, medical helicopters consistently have higher rates of fatal crashes per 100,000 flight hours than other categories of aviation (7). Crashes that occurred in darkness and poor weather conditions were more likely to result in a fatality (8). However, not all crashes involved patient care missions, as some occurred during maintenance flights and other operations. Among 131 crash-related fatalities between 1998 and 2008, 16 were patients being transported (7). This represents an estimated risk of 0.76 per 100,000 air medical transports (7). How this compares to

ground ambulances and their potential for crashes given similar distances traveled remains unclear.

Nevertheless, each tragic event serves as a reminder that air medical service utilization is not without risk. Safety risks should be considered carefully and weighed against perceived benefits. Strict adherence to safety standards is mandatory for both personnel on the ground and those in the helicopter.

The costs associated with air medical services are considerable. Medical helicopter bases may require $1.5 to $3 million per year to maintain, depending on the helicopter model, personnel qualifications, and abilities to achieve economies of scale. It is predominantly these fixed costs that determine the expense of providing air medical services. The incremental costs for a specific mission (the additional costs for providing service to one more patient) are approximately $1,000 to $1,500 depending on the aircraft model and distance traveled. Most of that relates to fuel consumption and aircraft maintenance. In Maryland, where most air medical services are provided by the state police, the cost of completing one mission has been estimated to be $5,000 (9).

Although the cost of providing air medical services may be significant, these costs are not necessarily unreasonable when compared to other alternatives. Air medical services, as a system, may cost less than providing similar care for interfacility transportation through a network of ground ambulances. Cost differences relate directly to helicopters' capacities to effectively serve larger geographic areas by virtue of speed and abilities to eliminate geographic barriers. The cost-effectiveness of air medical services has previously been determined to be $1,400 to $9,677 per year of life saved. For trauma patients, in particular, the estimate is $2,227 to $3,292 per year of life saved (10). A cost-effectiveness model based on more than 200,000 trauma patients indicated that helicopter transport must provide a 15% relative risk reduction of mortality, or 1.3 patients per 100, to cost less than $100,000 per quality-adjusted life year gained (11). Such a cost is consistent with those for other societal healthcare priorities.

AVIATION ISSUES

Because air medical services are a tool for providing clinical care, it is helpful for physicians to understand some of the inherent aviation issues. The most relevant factors are the limitations of the aircraft and the limitations of the pilot. Weather is a consideration for both.

Medical helicopters are either single- or twin-engine turbine powered aircrafts. Twin-engine outnumber single-engine aircrafts for air medical use. They are generally felt to be safer by virtue of mechanical redundancy. However, it is not clear that the number of engines greatly affects the safety profiles of air medical services. Helicopter crashes with mechanical causes rarely have to do with engine failure. Helicopters generally travel between 100 and 160 miles/hr, with useful loads of 1,500 to 3,000 lb. The concept of *useful load* is important; it includes all the medical equipment and helicopter crew. The useful load can also be affected by weather conditions, the amount of fuel on board the helicopter, and the mean sea level altitude of the helipad from which the helicopter will be departing. All of this determines the weight of the patient who can be transported and the equipment, personnel, or family that may accompany him or her. Patients may be heavier if the helicopter crew is lighter, there is less equipment, there is less fuel on board, the weather is cooler and less humid, and the helipad or landing zone is closer to sea level.

Medical helicopters may not operate in icing conditions; this can be catastrophic if not avoided. Thus, operations in some forms of precipitation are not possible. Flight through clouds might not be possible depending on the air temperature.

Most air medical services operate under visual flight rules (VFRs), limiting the required equipment on board, the helicopter, and pilot qualifications. VFRs require visibility to be 1 mile during the daytime and 2 miles at nighttime and a cloud ceiling (distance from the ground to the base of clouds) to be 500 ft or higher. Local conditions, including topography, may necessitate the visibility and ceiling to be greater.

Some air medical programs are capable of operating under instrument flight rules (IFRs). As the term implies, the pilot flies the aircraft by reference to onboard instruments instead of outside visual clues. The general limitation of IFR operations is the necessity to fly from one airport to another one at which there is a bona fide instrument approach developed to facilitate landing in marginal or poor weather conditions. Thus, patients must be first moved to, and then from, an airport to travel via helicopter. This is obviously time-consuming, eliminating some of the benefit of air medical service. GPS technology enables development of instrument approaches to locations other than airports, including hospital helipads. Although these are not widespread, a few air medical services have developed GPS approaches to serve places they often are requested to respond to in suboptimal weather conditions.

The pilot is the lynch pin of air medical service operations, as he or she is ultimately responsible for the safety of the crew and aircraft. Potential for pilot fatigue should be monitored, as it may adversely affect performance. Pilots' decisions regarding aviation issues must be made in the absence of knowledge of clinical circumstances, which may be compelling and inappropriately bias the process. Pilots must maintain the authority and responsibility to make safe decisions and should not attempt to complete a transport mission in unsafe conditions.

One of the factors thought to make air medical service operations more dangerous is the need to land helicopters at makeshift landing zones. Ground personnel usually have variable experience in setting up landing zones and conveying information about hazards to the helicopter pilot. Pilots may be unfamiliar with the area and surrounding hazards and may be distracted by adjacent activity and lights. One solution is to develop predesignated landing zones that EMS and public safety agencies preferentially use. The air medical service can then have pre-existing knowledge about potential hazards, and the landing zones can be set up systematically when needed. Another advantage is pilots' familiarity, and established locations are easier to navigate to and identify.

In some regions, fixed-wing aircraft may be valuable components of air medical services. They are usually twin-engine propeller or jet engine aircraft, capable of cruise flight between 200 and 400 miles/hr. Their useful loads are generally thousands of pounds, and their range is much longer than helicopters. Another advantage is their ability to fly in more adverse weather conditions than helicopters can. Fixed-wing aircraft fly from airport to airport, necessitating ground transport legs on each end of the patient flight. Thus, a fixed-wing aircraft is used to save time when the transport distance is usually 150 miles or longer. Fixed-wing aircraft often cruise between 14,000 and 30,000 plus feet above the ground. Their cabins are typically pressurized to the equivalent of 4,000 to 8,000 ft above mean sea level.

MEDICAL ISSUES

Medical issues relate to the interplay between patients' clinical conditions and physiologic effects of flight and the capacity to initiate or continue care during air medical transport. When emergency care practitioners appreciate these issues, they are better able to select appropriate patients for air medical transport and prepare them for that event.

Flight physiology is a discipline unto its own. Two concepts are particularly germane to ill or injured patients. First, as altitude increases, atmospheric pressure decreases and gases expand. The result is that gas-filled spaces expand. For seriously ill or injured patients, critical spaces might include pneumothoraces and the gastrointestinal tract. Additional air-filled spaces that the air medical crew must be cognizant of include patients' middle ears, endotracheal tube cuffs, air splints, and intravenous fluid bags. Second, as atmospheric pressure decreases, the partial pressure of oxygen decreases. The proportion of oxygen in the air remains constant (approximately 21%). However, because the total atmospheric pressure is less at higher altitudes, so is the pressure of oxygen within the mixture of gases that comprise air. Because the solubility of a gas (i.e., oxygen) within a liquid (i.e., blood) is

proportional to the partial pressure of the gas in contact with the liquid (i.e., within the lung alveoli), a patient's ability to remain well-oxygenated decreases at higher altitudes.

Most air medical transports via helicopter are conducted within 2,500 ft of the ground. Thus, the physiologic effects of flight are limited. However, by merely ascending 2,000 ft above the ground, patients' oxygen requirements are increased by approximately 8%, and air-filled spaces will increase in volume by approximately 8%. Previous guidance suggested that a patient with a known pneumothorax should receive a thoracostomy tube prior to air medical transport. However, one model of pneumothorax found 1.5% increase for every 500 ft ascended (12). Thus, knowledge of local air medical services and their practices can help a referring physician consider the risks and benefits of placing a chest tube in the context of the clinical situation and physiologic changes that might occur in flight. A stable patient with a modest pneumothorax who is going to be taken to 1,500 ft above the ground might be considered for close observation during transport. A different patient with a larger pneumothorax or who is going to be taken to 5,000 ft above the ground should perhaps receive a chest tube before transport. The objective is to diminish the potential for precipitous deterioration as a result of pneumothorax expansion from the primary injury in conjunction with altitude changes.

Additionally, seriously ill and injured patients should receive supplemental oxygen during flight. It is important to understand that if there is difficulty in achieving adequate oxygenation on the ground, the problem will only worsen during air transport. There must always be the capacity to increase the supply of oxygen to patients during air transport beyond what they were receiving on the ground.

When patients are transported in helicopters operating in IFR conditions or in a fixed-wing aircraft, even more attention must be paid to the physiologic effects of flight. Helicopters operating in IFR conditions are often 5,000 or more feet above the ground and, as noted, fixed-wing aircraft cabin pressures are usually equivalent to 5,000 to 8,000 ft above mean sea level. Thus, the potential for air-

filled spaces to expand and patients' oxygen requirements to increase are significantly greater than during low-altitude helicopter operations. One specific group of patients for whom this is a concern are those with dysbarism related to scuba diving. Decreases in the atmospheric pressure to which they are exposed, whether via commercial air travel or air medical transport, can cause precipitous deterioration.

Other important factors include effects of vibration and decreased temperature and humidity as altitude increases. Air medical crews must be cognizant of patients' exposure to ambient air. Ill patients who might lack intact thermoregulation may be susceptible to rapidly changing air temperature as altitude changes. The adiabatic lapse rate results in approximately 2°C temperature decrease for every 1,000 ft ascended. Crews must also be aware of the need to monitor possible and insensible fluid loss, particularly among patients receiving nonhumidified oxygen. Finally, aircraft vibration and noise are thought to create a potential for autonomic instability in critically ill patients.

The capacity to monitor patients' conditions and initiate and continue care during air medical transport should be a constant concern. It is partly the difficulty in monitoring patients that prompts pretransport placement of thoracostomy tubes for patients with pneumothoraces. In helicopters and many fixed-wing aircraft, breath sounds can be difficult to hear, blood pressures can be difficult to auscultate, weak pulses can be difficult to palpate, and patients can be difficult to communicate with. Cardiac monitors, pulse oximeters, noninvasive blood pressure monitors, and capnographers facilitate patient monitoring, but none are entirely foolproof. Air medical crews must continuously assess the quality of data before interpreting and relying on it.

The ability to continue ongoing care is usually a function of its complexity and the qualifications of air medical crews. The most common emergency medicine–related examples relate to airway adjuncts and ventilation. It is important to be familiar with the types of airway adjuncts that an air medical crew is trained to use. For example, the crew might lack working knowledge of laryngeal

mask airways (LMAs) and would not be prepared to manage a patient with an LMA in the event it becomes dislodged. They might not be prepared to continue transtracheal jet ventilation. They might also be limited in their abilities to deliver specific modes of ventilation via mechanical ventilator or continuous positive airway pressure support to a spontaneously breathing patient. In such cases, air medical transport might be inappropriate, or modifications to ongoing care or support might be indicated. Another frequently encountered scenario involves ongoing medication infusions that require more intravenous pumps than the aircraft carries. Subsequently, decisions must be made about which medications to continue during transport and which to either hold or infuse without the regulation of a pump.

The ability to initiate new care is obviously limited by the available equipment and supplies within the helicopter or fixed-wing aircraft. The close quarters of an aircraft, limited access to the patient, and sometimes cumbersome access to available supplies can make initiating new therapy more difficult in the air than on the ground. Initiating intravenous access and administering intravenous medications are not too difficult. However, providing new airway support, although possible in most cases, is a task best completed on the ground. Conditions in a helicopter for tracheal intubation are far from ideal. Adult patients are not easily repositioned, and their heads often rest between the caregiver's legs. Thus, in cases in which a patient's airway stability is in question, the airway should be definitively secured before the patient is loaded into a helicopter, the procedure location of last resort.

Combative or uncooperative patients present a special dilemma. The cause of their agitation can be multifactorial, but the ability to address it while airborne is quite limited. Additionally, in such a condition, these patients present a significant risk to themselves and the helicopter crew while airborne. Thus, agitation must be dealt with prior to air medical transport. The risk of oversedation may be a concern due to difficulties in addressing airway instability should it subsequently occur. Therefore, many agitated patients are best

dealt with by sedation, neuromuscular blockade, and tracheal intubation.

A typical dilemma for an emergency care provider who is preparing a patient for air medical transport is how to determine the appropriate amount of preparation. Some clinical situations are best addressed prior to transport. However, not every eventuality can be predicted, nor is it feasible to spend an inordinate amount of time trying. Presumably, air medical transport has been chosen in most cases because of its speed, and there is some urgency in moving a patient from one location to another. It is reasonable to consider the likelihood of potentially serious complications of transport and do what can be done quickly to attenuate that likelihood. Beyond that, excessive efforts to "stabilize" patients before transport, particularly trauma patients, may do more harm than good by delaying arrival at definitive care. There are times when additional stabilizing interventions are preferred prior to transport. For example, some neonatal or pediatric teams bring their expertise to the patient rather than moving the patient to their expertise. They may be able to provide additional care that improves the safety of transport without delaying the care the patient is being transferred to receive. As each case is a unique event, it must be considered in its own context. However, it is always prudent to think about the amount of patient preparation for transport that is necessary and appropriate.

ADMINISTRATIVE ISSUES

The organizational structures of air medical services vary considerably. In the United States, they may be part of public safety agencies, military services in some cases, hospital-based programs, or independent nonprofit or profit-seeking organizations. Likewise, funding sources for these entities vary. Public safety agencies, for example, receive some or all of their support from taxes or licensing fees. Hospital-based programs attempt to recover costs through revenues from patients and their insurance carriers. However, the hospital may provide a substantial subsidy to support the program. Although the air medical program itself might not be profitable, the

patients it brings to its affiliated hospitals may generate significant income for them. Differences in funding sources result in variation in billing procedures and amounts. Third-party payers ultimately decide what appropriate compensation they are willing to provide for air medical services.

Selection of aircraft has multiple implications for air medical services. Helicopters routinely adapted for medical transport have varying characteristics. They differ in terms of size, performance, and operating costs. These result in variation regarding the types of patients and the associated equipment that can be transported. Aircraft size obviously affects interior design. With space at a premium, it is vital to consider equipment and supply needs and their optimal organization to facilitate patient monitoring and treatment. Interior layout among various aircraft even affects abilities to perform cardiopulmonary resuscitation. Ideally, from a physician's perspective, every aircraft would have an abundance of equipment and supplies, with redundancy, to enable optimal reaction to every eventuality and have enough interior room to maneuver about the patient. However, then the aircraft would have to be so large with performance characteristics that it would, for most services, make it prohibitively expensive to operate. Thus, the balance among aircraft performance, size, and cost to operate is important.

As the missions of many air medical services are diverse, so too may be medical direction. Medical directors have evolved from several disciplines, although emergency physicians make up the majority. Mission profiles of air medical services vary considerably. Those that include neonatal patients, complex pediatric medical cases, cardiac surgery patients with invasive assist devices, and other complicated or special populations often necessitate the appropriate inclusion of multiple physician advisors in the medical direction process. They bring added expertise and support for the service, helping to ensure the delivery of optimal care. Similar to the medical direction of a local EMS system, an air medical service medical director should have working relationships with regional

emergency clinicians to ensure excellent communication that facilitates continuous efforts to improve care and service.

Paramedics, nurses, respiratory therapists, and physicians serving as medical crew members typically deliver care using extensive protocols and standing orders. However, the communications system must function effectively so that field personnel can request and receive prompt and qualified online medical direction when indicated by clinical circumstances.

In most cases, the medical crew is composed of a flight nurse accompanied by another flight nurse, paramedic, or respiratory therapist. Part of their sophistication results from intense orientation and continuing education and from their continual exposure to critically ill and injured patients. Several states allow for medications and procedures by flight nurses and paramedics that are not available to ground-based paramedics (13).

Several hospital-based air medical services have, at one point or another, included a flight physician as part of the crew. Less than 10% still do. Earlier findings suggested that nurse–physician teams reduced mortality from trauma to better than what was predicted, and achieved outcomes that were better than nurse–nurse teams. However, these results have not been reproduced (14). As systems mature, it is possible that nurses and paramedics gain valuable experience to the point that adding a physician provides little significant value. Physicians' technical skills rarely augment the proficiency of nonphysician flight teams (15). Although physician judgment has been shown to make important contributions to treatment (15), it is possible that improved protocols and standing orders and communications systems that enable reliable online medical direction have negated some of that benefit.

Air medical services are often called to special situations where added expertise is valuable. Among these are transports involving neonatal or special pediatric populations. Working knowledge and technical competence with the specific needs of such patients is helpful in effecting safe transport to tertiary care centers. Neonatal and pediatric transport teams, supplementing or supplanting the routine air medical crew, often bring expertise in dealing with small

patients, including IV access, appropriate medications and doses, ventilatory support, and other special equipment.

Ensuring the quality of air medical services is a significant challenge with several facets. There are customer service dimensions involving interfaces between the air medical service and calls for help, EMS and public safety personnel, and hospital personnel. There are aviation-related dimensions focused on aircraft maintenance, pilot proficiency, and safety initiatives. And there are patient care dimensions focused on processes of care and outcomes.

Improving air medical service quality is a multidisciplined effort. Audits of certain types of cases and events may identify specific issues. Reviewing medical crew documentation provides only a limited perspective. However, involving the assessments of many of the people who participated in a case, both before and after the transport, helps to complete an appreciation of the entire event and identify areas for improvement in multiple dimensions. For this reason, many air medical services provide follow-up about patients to referral sources. Additionally, they implement systems or streamline processes that facilitate feedback to the air medical service when either positive or negative events occur and for receiving hospitals to provide outcomes' information that may be used to help assess utilization appropriateness.

To enhance safety and quality some air medical services have deployed crew voice recorders and video monitors in aircraft. While the practice might seem intrusive, the recordings have been used to clarify events, review unusual occurrences, and make improvements in aviation procedures, crew resource management, and clinical processes.

UTILIZATION REVIEW

An important aspect of quality improvement activity is utilization review. This should be a community effort to improve appropriate utilization of air medical services. Those who call on air medical services should review cases to determine their appropriateness and provide guidance to their staffs. Air medical services should review

their cases to provide guidance and feedback to referring agencies and hospitals.

Ideally, assessment of whether utilization of air medical services was warranted is based on some knowledge of the patients for whom it provided a difference. Unfortunately, this is not always entirely clear, although intuitively it makes sense in some clinical conditions. The most significant evaluations have been performed regarding trauma patients; however, these studies often suffer from limited sample sizes, selection biases, and confounding factors.

Previous investigations found reduced mortality among trauma patients when they were transported by a hospital-based helicopter as opposed to advanced life support ambulance. Among 150 trauma patients transported by helicopter and 150 by ground, mortality was 52% less than predicted in the air group, although it was higher than predicted in the ground group (16). The groups were not homogeneous, however. The ground-transported group was urban, and the helicopter-transported group was rural. A physician in the helicopter meant that initial patient-to-physician contact was sooner for the helicopter-transported group even though their arrival at the trauma center was later.

Among 1,273 patients transported directly from the scene by seven different air medical services, mortality was 21% lower than expected (17). Patients who were more seriously injured, with predicted survival less than 75%, benefited the most. The sicker the patient is, to a point, the more opportunity there is to benefit from an intervention. However, the factors that reduce mortality remain unclear. Although air medical services seem to provide a survival advantage for many trauma patients, the greatest advantage seems to be for the most seriously injured and those who are transported directly from the scene to a trauma center. Air medical response to patients with moderate to severe traumatic brain injury and subsequent transport directly to a trauma center is associated with improved odds of better outcomes (18). Further, among traumatic brain injury patients who underwent endotracheal intubation in the field, the odds ratio of mortality or poor neurologic outcome was

significantly higher if transported to the trauma center by ground ambulance as opposed to EMS helicopter (19).

Other studies have documented limited benefit when helicopter and ground-transported trauma patients were compared. When 15,938 helicopter-transported patients were compared with 6,473 ground-transported patients, there was no effect on estimated odds of survival (20). Another investigation yielded similar results after comparing 1,346 helicopter and 17,144 ambulance-transported trauma patients (21). There was a tendency toward improved survival among patients with higher injury scores, but most of the study population had relatively minor injuries.

Finally, an evaluation of the American College of Surgeons' National Trauma Data Bank examined a cohort of more than 200,000 patients taken to level I or II trauma centers by either medical helicopter or ground ambulance. Helicopter transport was found to have an absolute risk of mortality reduction of 1.5% (22). If true, then the number needed to treat, transport by helicopter instead of ground, to save one additional life is 65.

One reasonable conclusion to draw from the available literature is that air medical transport may positively affect outcomes among a subset of trauma patients: those who are more severely injured. Such patients are likely to have lower prehospital trauma scores and lower Glasgow Coma Scale scores. Thus, indicators of severe injury at the scene or community hospital ED may be reasonable indications for utilization of air medical services to transport a patient to a trauma center. An approach to achieving improved cost effectiveness is to utilize air medical services appropriately for patients at higher risk of death or poor outcomes, and to minimize their utilization for patients for whom they are not likely to make a difference (11). Ideally, each air medical service would strive to stay busy transporting patients for whom it might make a difference in outcomes.

The Association of Air Medical Services and the National Association of EMS Physicians have published criteria for appropriate use of air medical services (23). For trauma patients, consideration might be given to evidence of injury by virtue of

objective scoring systems, anatomic injury, or physiologic derangement; difficulty in accessing the patient by ground; serious mechanism of injury; and a significant increase in transport time. Many EMS systems have adapted these or similar criteria to guide decisions of whether to send or not send an air medical service to a scene.

Certain patients, by virtue of the extent of their injuries, are not appropriate for air medical transport. For example, patients who suffer blunt trauma cardiac arrest at the scene will not survive. Transport by helicopter will not change the outcome but exposes several people to the risk of flying and working around an operating helicopter (24).

For nontrauma patients, there is an even greater paucity of information regarding appropriate utilization of air medical services. Locally adapted guidelines might include cardiac patients requiring transport to receive emergency invasive reperfusion therapy, stroke patients being transported to receive emergency reperfusion therapy, neurosurgical patients who are to undergo emergency evaluation for potential craniotomy, high-risk obstetric patients with imminent complications, and tenuous pediatric and neonatal cases. In all such cases, there should be two overriding tenets: (a) The patient requires an emergency evaluation or therapy for a potentially life-threatening problem, and air medical transport saves significant time, or (b) the patient has a life-threatening condition such that ongoing care outside of an ICU is dangerous, and air medical transport significantly reduces the amount of time the patient will spend outside a controlled setting. Regional systems to care for acute myocardial infarction and stroke patients often rely on air medical services to get patients to the site for definitive evaluation and therapy within a defined window of opportunity (4,5). Though it may be possible to demonstrate the overall positive effects of such regional approaches to care, it is more difficult to single out the effects, if any, of air medical services' role. One simplistic view would be to determine what was possible only because the patient arrived to definitive care within a specific therapeutic window. For example, when air medical transport is the

only option for getting a stroke patient to time-sensitive reperfusion therapy within a defined window of opportunity, that might be appropriate utilization.

One approach to retrospectively assessing utilization appropriateness is to determine what critical interventions occurred during transport. The Therapeutic Intervention Scoring System serves this purpose. Previous estimates are that approximately 42% of air medical transports are indicated by virtue of the intensity of care required during transport or on the basis of objective scoring systems (25).

Continued evaluation by all stakeholders of air medical service utilization helps to ensure the appropriate allocation of resources. Just as some overtriage to trauma centers is expected (less injured patients being taken to trauma centers instead of other hospitals) to capture all the patients who might benefit, some overtriage to air medical transport should also be expected. However, to optimize cost effectiveness, it is necessary to keep air medical services busy transporting critically ill and injured patients who might benefit from them rather than keeping them busy transporting patients for whom there would be no benefit gleaned.

Consensus-created guidelines for utilizing air medical services are not equivalent to proof of effectiveness. However, such a proof does not exist for the many patient types routinely transported by helicopter or fixed-wing aircraft. Thus, such guidelines, when developed locally, represent one important basis for evaluating air medical service utilization.

Common Pitfalls

- Delaying helicopter transport by performing excessive efforts to stabilize the patient.
- Requesting air medical transport when it offers no advantage of time savings or safety for the patient.
- Delaying the request for medical helicopter transportation when it is appropriate.

- Failing to secure the airway prior to transport in patients in whom airway stability is in question or in combative patients.
- Failing to consider tube thoracostomy in patients with pneumothorax prior to transport in a helicopter.

CHAPTER 378 Disaster Planning and Management

Jonathan L. Burstein

In the past quarter century, disasters worldwide have claimed more than 3.4 million lives (1). As the world population increases and population density rises, a single catastrophic event may affect more victims simultaneously. Further, both the use of hazardous materials and population in hazardous environments (flood plains, earthquake zones, etc.) are rising. Disaster planning and response must include not only the ability to care for casualties but the ability to function in environments rendered dangerous or even actively hostile. The mission of the disaster responder is not only to render aid but also to restore society's homeostasis (2–7).

A "disaster" may be defined as a destructive event that disrupts the normal functioning of a community; it may be natural (e.g., Hurricanes Sandy or Katrina), technologic (e.g., chemical spill), or even deliberate (e.g., the 2013 Boston Marathon bombing, the September 11, 2001 terror attacks, the Madrid and London mass-transit bombings). Combinations of events can worsen the impact of each, such as the 2011 Fukushima nuclear plant disaster after an earthquake and tsunami in the area.

A medical disaster occurs when an event results in casualties that overwhelm the healthcare resources of the community involved (8). Many disasters, such as a jumbo jet crash without survivors, may not in this sense represent a medical disaster, although many slow-evolving events, such as pandemic influenza, may very well represent medical disasters. Response to a disaster may involve all

aspects and needs of a community, including restoring food, water, power, communication, and transportation networks. The role of the emergency physician in a response may not be narrowly limited to emergency medical care, as broader public health knowledge and organizational skills may be necessary, requiring emergency physicians to step outside their usual role of individual patient care and take more of a systems-management approach (9). In the largest-scale events, refugees and displaced populations can be both the result and the cause of disasters (10).

As noted, disasters are classified by origin. *Natural* disasters include earthquakes, floods, volcanic eruptions, hurricanes, tornadoes, winter storms, and other geologic and meteorologic phenomena; in this era of electronics, one may add the effects of solar storms disrupting pager and phone systems. *Human-caused* or *technologic* disasters include explosions, chemical spills, radiation leaks, biochemical terrorism, transportation accidents, civil disturbances, and armed conflicts. *Complex humanitarian* emergencies generally include features of both natural and technologic disasters, such as population displacement that results from a combination of drought, famine, and political upheaval.

In a model that is perhaps more useful for the planner, disasters also may be categorized by onset and impact. For example, earthquakes and tornadoes have a rapid onset, with a sudden impact on the community. In contrast, droughts and famines have a more gradual onset and generally have a prolonged impact. Numerous factors may modify the impact of a disaster on a community, including the nature of the event, time of day or year, health and age characteristics of the population affected, and the availability of resources. Planning for a sudden event should focus on responding with resources on hand, as opposed to the mobilization of resources that can occur in a slower-paced impact (11).

The impact of a disaster also depends on the location where it occurs. For example, an earthquake occurring in a sparsely populated area obviously injures fewer people. In contrast, a similar quake, even one of lesser magnitude, could produce extensive losses of life and property if it occurred in a densely populated region with

poor construction or limited medical resources. Additionally, many may be left homeless or without essential services. Even in the acute medical response to an event, a small community hospital could be easily overwhelmed by numbers and types of casualties that might be handled routinely by a large university hospital or metropolitan medical center (12). Hospitals can be resources in a response but also may be severely affected by the impact of a disaster, and the first priority of a hospital or other essential service must be to preserve its function so that it can play its assigned or necessary role in mitigating the disaster (5).

In the United States, although health care is generally provided by private-sector institutions, governments at all levels have both the responsibility and some capability of supporting disaster medical care. Town or municipal governments often regulate mass-casualty distribution and may coordinate the roles of local hospitals. State governments often serve as providers of funding and equipment, in a support role to local or county agencies, and provide a conduit to request federal aid. The federal government's main role is to provide funding for response, but there are also directly deployable federal assets (people, mobile hospitals, vehicles) available from the military, the Veterans Administration, and the National Disaster Medical System (NDMS). The NDMS has more than 30 specialty teams throughout the country that can deploy to provide field-hospital capability, including advanced specialty care (burns and pediatrics). These teams can be deployed within 6 to 24 hours of request by a state government. The NDMS also provides or coordinates patient evacuation and mass-fatality management (12,13).

DISASTER PLANNING

Disaster planning must address numerous types of events, ranging in scale from small mass-casualty incidents (MCIs), such as motor vehicle collisions with multiple victims, to extensive flooding or earthquake damage, to civil wars. The planning continuum includes advance preparations and provision for supplies, staff, and training

and actual event management and recovery efforts. Those people and organizations responsible for disaster plans must conduct extensive risk analyses, from the sanitation needs of crowds at mass gatherings to evacuation procedures for buildings and geographic areas to the threat posed by terrorist or military action that may be directed at an institution or its personnel (5,6,12,14).

Risk analysis is an essential feature of disaster planning in which a comprehensive inventory is created for all existing and potential hazards that are sufficiently likely to be a threat. Hazards may include such items as chemicals used by local industry, transportation elements such as airports and railroad stations, or collections of large groups of people in areas with limited access, such as high-rise office buildings, nursing homes, or sports stadiums. Environmental and meteorologic hazards must also be considered, such as the presence of fault lines and seismic zones and the seasonal risks posed by tornadoes, hurricanes, and snowstorms. Certain types of disasters can even be considered as "planned events" such as mass gatherings for sports or performance events or political conventions. These events require planning of the same type, although perhaps varying in detail, as do all other disaster responses (15).

Risk analysis should attempt to identify any groups of people at particular risk of injury or death or loss of property from each hazard and groups with particular needs such as children, the elderly, or the disabled. The estimated risk and patient load may vary by time of day, season, or location within a community. Properly conducted risk analysis necessitates the cooperation of corporate, governmental, and community groups to produce a comprehensive listing of potential hazards (1,12,16). It may be possible to reduce the relative risk posed by some hazards. For example, relocating a chemical depot further away from a school would reduce the risk that children would be exposed to hazardous materials.

The other essential step to take in planning is resource identification. Resources include both human and logistic elements, such as organizations with specialized personnel and equipment

(17,18). Disaster preparedness should include assembling lists of medical and paramedical groups, public works and other civic departments, and volunteer agencies, along with phone numbers and key contact personnel for each. Hospital departments should have readily available a complete record of all personnel, including home addresses and telephone numbers, accessible 24 hours a day. Local, state, or federal teams of responders may be available, and a planner must know how this aid can be activated or requested. In the realm of terrorism with weapons of mass destruction, highly trained and extensively equipped specialty teams may be an absolute need for effective disaster mitigation.

Effective disaster planning must occur at all levels, from local institutions to municipal, state, and federal governments, including private, volunteer, and international agencies (19). All groups should understand their own capabilities and limitations and those of the organizations with which interactions are anticipated or intended. The use of a hierarchical management system, such as the Incident Command System (ICS), to coordinate the information and resource management is essential for any large-scale disaster. The ICS is a command system for large-scale firefighting developed by the federal government, which has now been adopted under the name National Incident Management System as the standard system for all US public safety response agencies. Hospitals may choose to use a variant of the Hospital Emergency Incident Command System (a California-developed adaptation of ICS for hospitals) to function within the same structure as all other responding agencies (12). Disaster plans should be both structured and flexible, with provisions made for plan activation and decision making by field-level managers, if indicated.

Once a plan has been devised or a strategy outlined, it must be used and tested. Staff must be trained to carry out their roles in the plan. In general, the best plans assign to each person a role as close as possible to his or her everyday job: “Do what you always do, but faster.” A recurring problem in disaster response is “failure of communications,” but this often actually represents failure of coordination; the message may get through, but the person getting it

does not know what to do about it. True communication failures also may result from several conditions, including loss of infrastructure damaged by the disaster itself, and lack of operator familiarity, excessive demands, inadequate supplies, and lack of integration with other communications providers and technologies. Back-up communications systems, such as wireless, hardwire, and cellular telephones, may reduce the impact of disrupted standard communications. However, frequently, even advanced technology has been ineffectual or overloaded during disasters, pointing out the need for personnel to be well trained in their roles so they can function with minimal outside direction.

An essential step in planning and preparedness is the evaluation of the response, both to real events and after drills and exercises. Exercises to test plans are usually “tabletop” drills in which the responders gather around a tabletop and discuss their theoretical actions. More complex drills may involve activation of communications systems or transport of supplies or staff to different location. The most complex and helpful “functional exercises” may take the form of full-scale multijurisdictional exercises, using moulaged victims and requiring vast resources of supplies and personnel. A plan also may be assessed by computer simulations or seminar sessions focusing on key personnel or limited aspects of the disaster response, but generally this will be of minimal assistance in testing a plan’s real value.

The specific goal of any drill should be clearly understood in advance. If drills are to be used as training sessions and evaluations of preparations and response plans, personnel are more likely to make the correct or most appropriate response choices during the drill if they are prepared. Consequently, they will be more likely to take appropriate actions when faced with an unexpected disaster situation in the future. The more realistic the exercise, the more likely it is that useful information about the strengths and weaknesses of both the disaster plan and the responders will be acquired. The factor common to all disasters is a local shortage of available resources; without experiencing at least some of the stress which accompanies that situation, it is unlikely that the disaster

plan and response will be taxed at a level that realistically simulates the circumstances of an actual disaster.

Essential features of all effective disaster drills are the inclusion of all parties likely to be involved in the disaster response and a joint critique, with a formal debriefing of all participants after the exercise. This review should consider comments from all individuals, groups, or agencies involved in the drill. It is helpful, and essentially mandatory, to designate observers in advance to assess specific aspects of the plan, such as effectiveness of a phone tree or accuracy of medication dispensing. The observations and comments should result in modifications of the disaster plan, if necessary (20). A drill that produces no changes in plans or goals likely did not sufficiently stress the system. Any alterations in disaster plans or response procedures must be communicated to all groups involved or affected. Periodic evaluations of disaster plans are essential to ensure that personnel have adequate familiarity with their roles in disaster situations and to provide for changes in regional emergency response operations, hospital renovations and closings, and other variables. Hospitals have a requirement to conduct at least two disaster-plan exercises per year to maintain compliance with the standards of the Joint Commission on Accreditation of Healthcare Organizations (12,21).

Mass gatherings provide a unique form of “planned disaster.” In general, they will occur in a defined location such as a sports stadium, concert hall, waterfront, or field. Planning should include basic sanitation needs, hydration and environmental protection (against sun, heat, or cold exposure), and both routine medical care (acetaminophen and abrasion care) and full emergency care (cardiac resuscitation). Additionally, planning must address the medical response to a mass-casualty event at the scene, such as might be caused by a vehicle accident or terrorist attack. Staffing for a mass gathering is generally composed of a mix of provider types and levels (first aid, emergency medical service [EMS], nurses, physicians, security, fire, and rescue), a mix of venues (first aid stations, medical tents, ambulances), a mix of roles (on-scene care, evacuation, command and control), and a mix of jurisdictions

(private providers, public safety, city authorities, venue staff, state or federal authorities). This complexity makes preplanning critical for success. In terms of types of patient encounters to be anticipated, the best guide is prior experience at the same event, if available (such as recurring races, sporting events, or concerts). Some data are available in the literature, but the numbers are highly variable. In general, patient volume will be higher in outdoor environments, with younger average crowd age (confounded by event type) and with the increased use of alcohol or other substances in the environment (15,22). It may be appropriate to plan for care of victims of terrorism or other causes of mass casualties at an event.

DISASTER MANAGEMENT

The philosophy of disaster management may be summed up in the phrase, "The needs of the many outweigh the needs of the few." Resources may be so limited that stringent rationing of care or supplies is vital to the survival of the maximum number of people. Austere conditions may be alien to responders accustomed to ample quantities of medical supplies, equipment, personnel, and time, but they are commonly encountered with many large-scale disasters. In this setting, difficult triage decisions must be made to ensure that all resources are used in the most efficient and pragmatic manner (5,22).

The goal of disaster management is to provide the most appropriate intervention and assistance based on the most accurate information available in a timely manner. Disaster response includes several phases (Table 378.1) but must begin with recognition that disaster conditions exist. Some disasters, such as hurricanes, may be preceded by a period of time, called the *preimpact phase,* during which advance information may be gathered about the potential effects of the disaster. The data acquired during the preimpact phase may allow prepositioning of personnel and resources in a strategic location. As a result of a lack of verifiable data, it may be necessary, at times, to begin a response or asset deployment without full

intelligence, with efforts made to tailor and modify the response as updated information becomes available (23).

TABLE 378.1
Components of a Disaster Response

Activation
Notification and initial response

Response
Organization of command
Search and rescue
Victim triage, stabilization, and transport
Mitigation
Definitive management of scene hazards and victims
Recovery
Scene withdrawal
Return to normal operations
Debriefing
Updating and improving plans and planning
Drills and exercises

The EMS and hospital responders must be aware that triage in a disaster is devoted to providing the greatest good for the greatest number, rather than maximal effort for each patient. Often, patients in cardiac arrest who would normally have received a great deal of care are instead triaged as “expectant” (not resuscitated) so that the personnel and supplies saved may be used to help numerous other salvageable patients. The presence of toxic substances or radioactive materials may also change triage priorities (e.g., severely injured and heavily irradiated patients may be unsalvageable in a disaster setting). There are numerous methods for rapid triage that have been devised, such as the “START” (Simple Triage and Rapid Transport) system, and planners and responders should be familiar with the system in use in their area or institution (12).

Inevitably, in the event of a disaster that produces significant morbidity and mortality, including psychological threats and fears

resulting from terrorist actions, the physician on duty in the emergency department will be one of the first people called on to assume a leadership role. The existence of a hospital disaster plan provides a valuable resource but, ideally, the emergency physician should already be well versed in the administrative and logistical aspects of the plan and the purely medical functions. The response will evolve more smoothly if the emergency physician understands both the hospital plan and resources, capabilities, and disaster plans of the first responders and EMS system in the region. The physician may be required to coordinate or facilitate the hospital response and to provide direction for numerous aspects of the regional response and may be looked to as a resource for hospital administrators who want to know "What should I do?" The physician may also be consulted regarding the need for the deployment of agencies and resources from outside the affected region and will need to know where to direct these inquiries, because they are unlikely to have the knowledge to appropriately answer them. Additionally, emergency department staff should expect to be bombarded with requests for information on all aspects of the disaster and response —from family members, media, and government representatives and from the public at large—and be prepared to refer or respond to such questions. Early in a disaster, the emergency physician and staff will likely be expected to disseminate information about the disaster event, demonstrate expertise and leadership in the response and management efforts, and even make the initial determination that disaster conditions exist. Hospital administrators, social services, and public relations personnel will need to assume their proper roles to allow the ED to continue to provide medical care and should be notified as soon as a disaster is recognized.

In the case of damaged or destroyed healthcare facilities or after a large-scale disaster, the physician may also be called on to provide medical care in unconventional settings. In the situation in which field medical care stations must be established, coordinating responses with other agencies is essential. It is important to remember, during the early stage of the disaster, that information available from those at the disaster area (data regarding death,

injury, or damage) may not be accurate. Problems with communications are frequently the source of delays and misapplications of disaster resources. The ability of those in a region devastated by a disaster to survey the population and infrastructure may be severely curtailed by damage, such that even initial calls for help may be impossible. It is essential, therefore, that external resources of personnel and equipment be available and accessible if anticipation of potential need for them arises (5,22). Conversely, as a result of disruption of communications and transportation, it is possible for the effects of the disaster to be overestimated. To minimize damage and disruption, expedient decisions must be made, with future consequences of such actions considered as well. Short-term benefits and costs must be weighed against their long-term counterparts. Disasters are costly events, but judicious initial expenditures may result in substantial savings, in both monetary and humanitarian terms, over the long haul. Conversely, excessive spending by individuals, agencies, or organizations may result in prolonged or delayed recovery from the disaster and may restrict the capability to prepare or respond when the next disaster strikes.

In the case of a disaster that causes substantial destruction of infrastructure, the response may be prolonged, requiring that long-term healthcare and support services be established. Issues such as nutrition evaluation and ongoing disease surveillance may require the expertise of numerous other healthcare providers and agencies. Additionally, mental health issues must also be considered for the victims and the responders during both the emergency phase and the recovery. Posttraumatic stress disorder, major depression, generalized anxiety disorder, and substance abuse are frequently reported among disaster survivors who have experienced traumatic bereavement or severe disruption of their lives. Early and voluntary access to mental health workers for evaluation and intervention may reduce the incidence and severity of such reactions (2,24).

Common Pitfalls

- Failure to prepare for a disaster by identifying potential hazards in the local environment and hazards that may be brought in, whether by nature or human action.
- Failure to develop appropriate multiagency and multijurisdictional contingency plans.
- Failure to properly exercise and update disaster plans.
- Failure to appreciate that disrupted communication and transportation systems frequently cause problems in assessing and responding to disasters and that redundancy of equipment, training in its use, and flexibility of use of communication and transportation resources are desirable.
- Failure to consider the needs of the elderly, children, and other special populations and to include such things as appropriate medical supplies, diapers, formula, medications, interpreters, and special transportation requirements in disaster planning and response.
- Failure to appreciate that disaster responders may become casualties themselves, that they may suffer psychological effects during and after the event, and that personal planning and institutional support are crucial to minimize the impact of disruptions in the personal or professional lives of disaster responders.

PART 2 • PATIENT SAFETY, ETHICAL, LEGAL, AND REGULATORY ISSUES

CHAPTER 379
Errors and Patient Safety

Robin R. Hemphill

Patient safety may be defined as those events that should never happen to patients as they interact with the health system. Put more eloquently, patient safety is a dynamic nonevent. Despite increased attention, patients continue to be harmed by the very system that intends to heal them. The emergency department (ED) setting is a particularly challenging arena and is prone to errors for a variety of reasons (Table 379.1).

TABLE 379.1
ED Conditions Conducive to Errors

1. Limited information creating diagnostic uncertainty
2. Cognitive overload
3. Low rate of serious conditions hidden within high rates of less serious disease (low signal to noise ratio)
4. Requirement for rapid decision making
5. No prior relationships with patients
6. Difficulty with continuity of care
7. Overcrowding
8. Limited feedback
9. Shift work contributing to fatigue
10. Understaffing
11. Multiple interruptions
12. Variation of team members
13. Excessive noise
14. Multiple transitions of care

Opportunity to improve may come from those industries that are recognized as High Reliability Organizations (HROs). These organizations are ones that are at high risk for hazard, yet have

lower rates of accidents and adverse events than one would expect given the complexity of their operations. Examples include the airline industry, aircraft carriers, and nuclear and chemical plants. Weick and Sutcliff (1) have studied such organizations and find that all have five things in common: preoccupation with failure, reluctance to simplify, sensitivity to operations, commitment to resilience, and deference to expertise.

While the healthcare system is not identical to any of the industries mentioned, a framework can be developed to help operationalize these concepts (Fig. 379.1). A successful journey to high reliability must balance across all of the elements in this diagram.

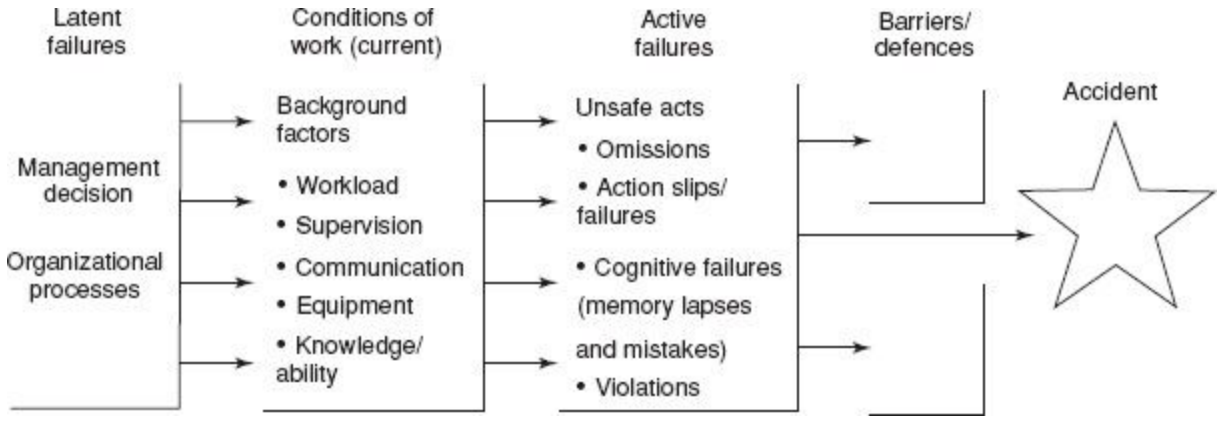

FIGURE 379.1 Anatomy of a complex accident. (Reproduced with permission from Vincent C, Taylor-Adams S, Stanhope N. Framework for analysing risk and safety in clinical medicine. *BMJ*. 1998;316(7138):1154–1157.)

FRAMEWORK FOR HIGH RELIABILITY IN HEALTH CARE

Culture of Safety

Put simply, a safe culture is one in which those in charge are willing to hear bad news and act appropriately. Developing such a culture is a central element of efforts to improve both the safety and the quality of care provided to patients (2).

Just Culture

A Just Culture is one in which the line between acceptable and unacceptable behavior is clearly stated. It recognizes that individuals make mistakes and acknowledges that even the most committed professionals will develop unhealthy norms (short cuts, rule violations, etc.), but has no tolerance for behaviors that are repeatedly or purposefully harmful (3).

When an error or adverse event occurs, rather than asking “who is at fault,” a Just Culture asks “why did this happen.” Human error can be viewed in one of two ways: (1) It is the fault of the people working in the system (violations of procedure or policy, loss of situational awareness, careless or poorly trained individuals) or (2) it is a symptom of a system that has latent vulnerabilities dispersed throughout it. Latent failures are faults created by policies, directives, or decisions that have been made remote from immediate patient care settings. These latent failures typically occur at higher levels in the organization and they may be difficult to see until such time that they combine with other active failures and triggering factors that together combine to overwhelm barriers put in place to protect patients. This results in a near miss or actual harm. Examples of latent failures specific to the ED setting include hospital policies that impact patient flow in the ED, high patient volume resulting in cognitive overload, multiple interruptions, limited patient information, inadequate staffing, frequent overtime or long shifts, complex medical equipment, limited standardization of medical equipment, and challenging computer interfaces, among others.

If the assumption is made that individuals do not come to work with the intent to cause harm, then it is important to move beyond blaming the individual and instead look for the system vulnerabilities (latent errors) that have contributed to the adverse event. HROs do not look for the first or most simple answer found when considering adverse events; they dig below the obvious to find and correct the latent problems within the system that if uncorrected will likely cause another similar adverse event in the future. If the individual involved is blamed and punished for the error, it is unlikely that underlying contributing factors will be

found. Furthermore, others who witness the punitive action will be unlikely to disclose their own errors or near misses. Opportunities will be lost to focus on and understand failures and near misses and we will continue to blame people who find themselves at the end of a series of events (environmental and design, and occasionally policy) that make it very easy to do the wrong thing.

It is important to note that a Just Culture does expect accountability for acts that are indeed blameworthy. Individuals who purposely violate policies intended to protect patients should be counseled and disciplined appropriately. Furthermore, accountability in a Just Culture expects managers and supervisors to address problem employees before they make an error that harms a patient, rather than waiting to act until a problem employee makes an error that might have been prevented.

It is questionable whether we can fully understand the intention of an individual when an adverse event has occurred. When reviewing an error that has harmed a patient, it is almost impossible to avoid “hindsight bias” (i.e., once the outcome is known, overestimating the clarity of events to those involved at the time) and some events can be seen to rise to the level of a willful disregard for patient safety. But such confident leaps should be approached cautiously. Iatrogenic harm is not necessarily caused by the random collision of independent failures, human errors, and intentional behaviors. Rather, it often results from a systematic migration of organizational behavior caused by the stress of operating in an underresourced and demanding environment where cutting corners to improve efficiency is not only valued, but openly celebrated. The more success that is attained at this limit of safe operating capacity, the more accepted (and even expected) it will become until a tragedy occurs. This is called the normalization of deviance, and is difficult to appreciate as it is happening. Only in hindsight is it clear that limits were being pushed well beyond what was safe. At that point there is often a single individual who appears to be at fault.

Engaged Leadership

Leadership is the driving force behind a safety culture and senior leaders have the responsibility as well as the authority to make safety a priority. It is critical for leadership to make safety part of the daily discussion and a center point of major meetings and strategy sessions (4). Frontline staff will believe that safety is important to the organization's senior leadership if those leaders visit the departments where the work occurs (leadership walk or sit rounds) and engage directly with the staff about what they see and what their concerns are. This allows for a cyclical flow of information (5) from staff to leaders and back. Leadership in the ED should also show support for directives and policies that enhance safety (time outs, checklists, follow-through on actions after root cause analyses (RCAs), daily safety huddles, etc.). It is also important for leadership to support the transparent reporting of adverse events to affected patients and families. Finally, leadership will determine the response to adverse events and should establish nonpunitive reporting systems, as well as help providers recover from the emotional distress they may feel after being involved in an event that harmed a patient.

High Functioning Clinical Teams

Medical training is competitive and not necessarily conducive to the development of team behaviors. The assumption that individuals will by themselves emerge from their training environment with team skills is not justified. Developing truly high functioning teams takes training and practice.

Health care is provided by teams of individuals with specialized knowledge, skills, and roles but who should share a common goal in patient care. They are dependent upon one another and their actions need to be coordinated to achieve the desired goal. Members of the team must have a shared mental model that allows each person to maintain situational awareness, the continuous perception of the team in relation to its dynamic environment, and the perceived ability to make adjustments. It includes being aware of critical

information, comprehending the meaning of this information, and planning for future possibilities (6).

Much of the recent work in improving team performance in the medical environment has been based upon the aviation model of Crew Resource Management (CRM). Multidisciplinary training in CRM teaches behaviors to help manage human error. This includes team practice behaviors to avoid error (marking a site, conducting a briefing, checklists), team practice behaviors to trap error (closed loop communication such as read-backs, redundant double-checks, and timeouts as a final check that ensure that the message transmitted is the message heard and acted upon), and team practice behaviors to mitigate the consequences if an error affects the patient (immediate reporting of errors which act to reduce the impact of an error). Achieving such levels of performance requires individuals to learn both leadership and follower behaviors, including an understanding of how leadership styles can impact team performance as well as skills to bring critical information to the attention of team members. In the operating room, these behaviors along with a checklist-guided team briefing that precedes every operation have been a cornerstone of improved outcomes. Critical information is shared, reviewed, and confirmed by the team. Any concerns or questions can be addressed prior to the start of the case. Potential complications can be reviewed and anticipated. In the operating room these briefings have resulted in improved perceptions of teamwork, prophylactic administration of antibiotics, and deep venous thrombosis treatment (7), as well as decreased operative mortality (8). While much of the work thus far has been in the surgical literature, success has been noted in a variety of clinical settings. These techniques may also be applied to the ED setting (9,10). For example, in cases of care delivered to a critically ill patient, the provider can discuss what the diagnosis is thought to be, the treatment options chosen, and a brief review of what the team should see if the patient responds, as well as what might occur if the early diagnosis is incorrect.

Understanding Complexity and Improving the Environment of Care

Health care is complex. This means that it consists of interdependent and diverse components that adapt to changes in the environment and is distinct from complicated systems that are not able to adapt to change. For example, one's car is complex and has many interdependent parts, but if it runs out of gas, it cannot adapt in some way to keep running. The ED on the other hand has many interdependent parts, but if it is poorly staffed, it does not shut down, it adapts. This means that even the best of intended changes can ripple through the system and manifest in unexpected, and occasionally harmful, ways. If one understands that the components of the healthcare system will interact with and adapt to changes and barriers, it should be clear that a culture that values the reporting of errors, concerns, risks, or near misses is imperative to prevent or mitigate harms that may emerge in this system. The only way to identify these harms, however, is for the organization to be willing to discuss and face its problems. This is why the Just Culture is so critical if we are to improve patient safety. If individuals are punished for errors, the problem may appear to have been solved, but organizational failures almost never have a single cause. Unless the latent errors that contributed to the problem are uncovered, adverse events will likely recur. When near misses or error occur, these incidents should be understood to present opportunities to learn from the event. Tools such as RCA may be used to more fully understand and identify the system vulnerabilities that may have contributed to an adverse event or near miss. The RCA process helps identify root and contributory factors that led to the event and then recommends strategies to reduce future similar events. Other tools, such as healthcare failure and effect analysis (HFMEA), offer opportunities to assess for system vulnerabilities before a close call or adverse event occurs. This tool allows a team to map out a high-risk process and assess its vulnerabilities so that mitigation steps can be built into the system. Each of these tools offers the possibility of recognizing contributors of harm and responsing with efforts to

improve the environment of care. In the case of RCA, the lessons learned are retrospective but can still be very helpful. Over time these reporting systems can help identify problems at the macro system level and so large-scale improvements can be considered. Such improvements should be informed by the use of human factor techniques when possible, so that the system is designed taking into account an understanding of the causes of human error and an emphasis on making it easier to do the right thing. For example, a common error in anesthesia practice was to accidentally attach the tubing designed to deliver oxygen to the patient to the wall valve that delivered only air. When the valve was redesigned to make it difficult to attach oxygen tubing to the air valve, the problem was largely eliminated. While such redesigns of systems present distinct challenges and are not always possible, this type of solution should be the goal. Interventions such as training programs and letters of reprimand will not improve safety comparably over the long term.

CHALLENGES TO MEASURING SAFETY

The Centers of Medicare and Medicaid Services has defined "never events" and it is fair to classify these as breakdowns in safety. At a single institution such cases are thankfully rare. Thus, it can be challenging to answer the simple question as to how safe an individual ED is. A recent framework to help measure safety has been suggested and consists of five broad classes (11):

- Past harm: This considers whether patients have been safe in the past and might include mortality statistics, use of a global trigger tool (12), incident reports, RCA collections, and other sources indicative of past harm.
- Reliability: This asks whether clinical systems, processes, and behaviors are reliable. Examples include compliance with hand washing, medication error rates, or percentage of patients who are appropriately consented prior to a procedure.
- Sensitivity to operations: This attempts to determine how safe care is today and relies on individuals and teams maintaining awareness. Strategies to achieve this include safety walk rounds

(13), the designation of patient safety officers, and operational meetings, among others.
- Anticipation and preparedness: This attempts to determine whether care will be safe in the future. Examples include surgical checklists which force a period of reflection in which problems associated with the procedure can be reviewed, HFMEAs, and a focus on creating a culture of safety.
- Integration and learning: The focus here is on responding and improving. Examples of this might be the review of common contributors to errors found through RCAs used to improve processes or tools to reduce recurrence of similar errors.

Approaches to Improving Patient Safety

- Make a discussion of safety and quality of a part of every ED staff meeting.
- Commit to a Just Culture where adverse events and near misses are freely discussed without punishment and accountability processes are clearly defined.
- Engage in team training to enhance communication and to increase team situational awareness.
- Focus on improving the environment of care using human factors approaches to make it easier to do the right thing.
- Complexity is the enemy of safety—focus on ways to minimize unneeded hand-offs and process steps (e.g., transcribing physician orders into a computer increases the risk of error more than having the physician enter orders directly).
- Reduce reliance on memory—use checklists, algorithms, and clinical pathways, and allow easy access to current references.
- Standardize processes when appropriate.
- Focus on developing measures to determine how safe the care in the ED is.
- Review recent literature on safety strategies that are ready for adoption now and tailor those that are appropriate to the ED setting (14).

- Be familiar with The Joint Commission National Patient Safety Goals for 2013 and develop strategies to address those relevant to the ED (see Table 379.2) (15).

TABLE 379.2
2013 Joint Commission Patient Safety Goals Relevant to EM

Description
Identifying Patients Correctly: Use at least two ways to identify patients
Improve Staff Communication: Get important test results to the right staff person on time
Use Medications Safely: Before a procedure, label medicines that are not labeled
Use Medications Safely: Take extra care with patients who take medicines to thin their blood
Use Medications Safely: Record and pass along correct information about a patient's medicines
Prevent Infection: Use the hand cleaning guidelines from the Centers for Disease Control and Prevention or the World Health Organization
Prevent Infection: Use proven guidelines to prevent infections that are difficult to treat
Prevent Infection: Use proven guidelines to prevent infection of the blood from central lines
Prevent Infection: Use proven guidelines to prevent infections of the urinary tract that are caused by catheters
Identify Patient Safety Risks: Use proven guidelines to prevent infections of the urinary tract that are caused by catheters

Common Pitfalls

- Failure of leadership—failure to commit to development of culture and team development. Safety is not a person, it is an ongoing value that infuses all aspect of clinical practice.
- Resistance to standardization.
- Burying patient safety in the system—bad news needs to get to the top.
- Failure to understand that safety and efficiency are in tension—in our efforts to push the system to be more efficient we can begin to compromise safety. Many things seen as duplicative and wasteful are redundancies built into the system to maintain safety.
- Settling for easy answers rather than understanding.

- Overreliance on technology. Advances in technology have enhanced safety in many areas, but technology may add layers of complexity that increase the risk of errors.
- Failure to engage the patient. Patients and their families can be effective in identifying errors. They should be informed about the expected course of their ED visit and encouraged to ask questions and speak up when they perceive that something is not consistent with the plan that was discussed.

CHAPTER 380 Quality Improvement

Robin R. Hemphill

In contrast to "patient safety," which is concerned with those events that should never happen to patients as they interact with the healthcare system, quality improvement may be defined by concern about all the things that *should* happen to patients to increase the likelihood of desired health outcomes and to meet their expectations. This goal is challenging to achieve because it is so broad. In *Crossing the Quality Chasm,* the Institute of Medicine (IOM) has offered a blueprint that identifies and classifies the elements of quality through six desired characteristics of quality care (1):

1. Safe: Care should be free from preventable harms (see Chapter 379).
2. Effective: Evidence should be applied to the delivery of care.
3. Efficient: Resource use should be assessed in achieving desired results and waste should be removed.
4. Timely: Waits and delays should be understood and minimized.
5. Patient centered: The health system should focus around the goals and needs of the patient and respect the decisions and preferences of the patient.
6. Equitable: Disparities in care should be removed.

To achieve these, administrative leaders require a set of skills that focus on patients, the use of data, and the engagement of the healthcare workforce.

QUALITY IMPROVEMENT PROCESSES

Industry has developed a variety of systems to guide quality improvement efforts, many of which can be applied in the

emergency eepartment (ED) setting. The goal is to develop a system that consistently delivers the correct care to a patient at the best price in a manner that meets the patient's expectations. A guiding principle is that one must understand the goal to be achieved before determining how to accomplish it. Specific methodologies for improving quality are summarized in Table 380.1. Each follows a procedure of repeated testing and intervention.

TABLE 380.1
Comparison of Improvement Process Methods

	PDSA	Lean	Six Sigma
Process Steps	Plan, Do, Study, Act	Eliminate nonvalue steps, Value stream mapping Kaizen (continuous improvement)	Define, Measures, Analyze, Improve, Control (DMAIC)
Improvement Targets	Small tests of change to identify optimal process improvement opportunity	Eliminate waste, improve system flow	Eliminate variation and defects
Strengths	Useful when time and resources are limited and desire to test a theory prior to wide spread implementation	Useful when a clear process can be defined and appears to have nonvalue activities embedded in process	Useful when process variation should be minimized and the activity is high volume
Weaknesses	Changes done in isolation may cause unintended consequences downstream of the changes	Some steps seen as waste may be redundancies put in place to maintain safety	Reduction in resilience may occur if appropriate variation is minimized

IMPROVEMENT PROCESS METHODS

Plan, Do, Study, Act (PDSA) Cycle

This is a method of trial and error carried out over a series of small cycles (2). Small tests of change are attempted before proceeding with broader implementation.

- Plan: In this phase it is helpful to consider three questions (3):
  1. What are we trying to accomplish?
  2. How will we know change is an improvement?
  3. What changes might allow the desired changes to be achieved?
- Do: Carry out the plan on a small scale, identifying problems, and make other observations. Data analysis begins here.
- Study: Assess the effects of the initial change and compare them to those which were aimed for. Summarize the lessons learned and identify any further changes that appear to be needed.
- Act: Decide whether the cycle should be repeated with modifications or whether the initial goals have been achieved.

Note any remaining gaps in desired performance and determine whether additional PDSA cycles should be undertaken.

Lean Methodology

Lean thinking focuses on improving flow and reducing cost by removing activities or processes that use resources but create no value. This is referred to generically as "waste." This includes waste of over- and underproduction, waste of inventory (e.g., unused medications which may expire), waste of rework (e.g., redo of x-rays when poorly done), waste of motion (e.g., repeatedly checking to see if a patient has returned to a room after testing), waste of waiting (e.g., both providers and patients waiting on laboratory tests prior to disposition), waste of processing (e.g., decreasing steps of ED triage process), waste of transporting (e.g., excessive distance from the ED to the cath lab). Lean processes also focus on improving the delivery of services or products by aligning the best steps in the best sequence. Simplification of processes can result in less variation and more consistent output.

Six Sigma Methodology

Six sigma refers to a control process in which 99.99966% of outcomes are within the desired range of acceptability. Opportunities for improvement or for correction of problems are identified through a series of steps (DMAIC): Define the problem and the improvement objective, Measure each of the process steps, Analyze the collected data to provide insight into the process, Improve the process by developing solutions and changes, and Control the process if it is performing at the desired level, while continuing to monitor for unexpected events. This methodology is based on the idea that reduction of variation leads to both consistent output and improved efficiency.

QUALITY MEASUREMENT

Measures of performance are critical to the ability to improve. Appropriate quality measures are essential to improving care in the

ED setting and increasingly there is an expectation that performance data will be made available to the public. Emergency medicine providers currently have a variety of externally imposed quality measures (some of dubious value) (4,5), and there is a need to develop measures that better reflect the quality of care that emergency physicians wish to provide. The Centers for Medicare and Medicaid now require reporting of a variety of performance measures. Examples relevant to emergency medicine providers are listed in Table 380.2.

TABLE 380.2
2013 PQRS Measures Relevant to Emergency Medicine

Description
• Aspirin at Arrival for Acute Myocardial Infarction (AMI)
• Stroke and Stroke Rehabilitation: DVT Prophylaxis for Ischemic Stroke or ICH
• Stroke and Stroke Rehabilitation: Screening for Dysphagia
• 12 Lead ECG Performed for Non-Traumatic Chest Pain if >40 years old
• 12 Lead ECG Performed for Syncope if >60 years old
• Community-Acquired Pneumonia (CAP): Vital Signs
• Community-Acquired Pneumonia (CAP): Empiric Antibiotic
• Prevention of Catheter-Related Bloodstream Infections (CRBSI: Central Venous Catheter Insertion Protocol)
• Acute Otitis Externa: Topical Therapy
• Acute Otitis Externa: Systemic Antimicrobial Therapy- Avoidance of Inappropriate Use
• Stroke and Stroke Rehabilitation: Thrombolytic Therapy
• Heart Failure Left Ventricular Function Testing
• Anticoagulation for Acute Pulmonary Embolism
• Ultrasound Determination of Pregnancy Location for Pregnant Abdominal Pain
• Rh Immunoglobulin for Rh-Negative Pregnant Women at Risk for Fetal Blood Exposure
• Prevention Care and Screening: Screening for High Blood Pressure

When determining what to measure it is important to take into account how such measures will be used. Measures developed to help *understand* performance may later become measures used to *enforce* performance. This shift in use is unhealthy since it may induce providers to resist the development of other measures in the future.

Desirable characteristics of quality measures are listed in Table 380.3 (6).

TABLE 380.3
Desirable Characteristics of Quality Measures

Characteristic	Description
Relevance	The measure should be important and valuable to all involved stakeholders—providers, patients, payers (e.g., diagnostic accuracy would be relevant to all stakeholders)
Evidence-Based	The measure should link structure and/or processes to the desired outcome. When scientific evidence is avail-able it should be used to guide the quality measures being developed (e.g., delivery of certain treatments for specific diagnosis)
Reproducible	Once developed the quality measure should produce the same results when repeated over time (e.g., the time that an antibiotic is administered in the ED)
Valid	The quality measure should be associated with what it claims to be measuring (e.g., a computer-generated time stamp indicating when a patient is seen by an ED provider should accurately represent when the patient was actually seen by the provider, not necessarily when the provider signed up for the patient)
Feasible	The measures should be practical to collect (e.g., rates of diagnostic error is a relevant and important quality measure, but can be very difficult to determine)

APPROACHES TO IMPROVING QUALITY

- Meaningful engagement of physician leaders is critical if long-term gains are to be made in both quality and safety. Leaders give legitimacy to improvement efforts, tie them to strategic priorities, and can direct needed resources. Change will not be achieved by the efforts of only a few committed individuals on the front line. Quality and safety should be a part of every staff meeting.
- Emergency physicians should take part in the development of quality measures relevant to emergency practice. Performance data should be transparent and accessible. Decreasing practice variation may provide opportunities to improve patient care. Processes should be standardized when appropriate. This includes the use of clinical pathways.
- Initial ED improvement efforts should focus, whenever possible, on areas where there is widespread support for change.
- Patients and families may give physicians critical insight into ways they may improve the delivery of care in the ED.

- Develop strategies to understand and limit procedures and tests that are overused in the ED (7).
- A particular focus should be on improving transitions of care. This includes handoffs between emergency physicians during turnover, handoffs when admitting patients to inpatient settings, and the patient discharge process. Quality and safety are compromised by the limits of human cognition, particularly in the ED setting. A deeper understanding of how decisions are made may provide opportunities to recognize the limits of clinical judgment and to take this into account when designing ED protocols and procedures (8).

Common Pitfalls

- Failure of leadership. Just as leadership can support quality management, it can also obstruct it. The ED leader must constantly demonstrate visible support for the quality effort.
- Prioritizing physician autonomy over appropriate standardization of care.
- Using quality improvement measures as performance measures.
- Failure to develop meaningful performance measurements. Often things are measured because they are easy to measure, not because they matter.
- Failure to sustain gains made during improvement projects. It is important to cement gains that have been made before moving from one project to the next. Cooperation will wane if the work put into quality efforts does not result in long-term improvement.

CHAPTER 381 Legal and Ethical Issues

Dave W. Lu and James G. Adams

Ethical and legal issues are present in every doctor–patient encounter. They become more poignant in the emergency setting where decisions often need to be made in a time-sensitive manner and without all the necessary information available. The potential for retrospective scrutiny of actions performed in emergency settings can make decisions surrounding complex legal and ethical issues particularly challenging and stressful for providers. Emergency physicians nonetheless can successfully manage the most common legal and ethical dilemmas that arise in their practice with a thorough understanding of core legal and ethical principles. Legal and ethical conflict in emergency medicine usually involves issues regarding consent and refusal of care, dilemmas near the end of life, questions of decisional capacity, use of patient restraints, and patient confidentiality. This chapter presents specific situations in the emergency department (ED) in which legal and ethical questions are most likely to arise and offers frameworks to assist in decision-making.

CONSENT ISSUES

Autonomy is a core principle of medical ethics, and it is widely accepted that adults with intact decisional capacity have the right to accept or refuse recommended medical care. There are three types of consent important in emergency medicine: informed consent, general consent, and emergency exception to consent.

Informed consent by a voluntary patient with decision-making capacity gives a healthcare provider permission to proceed with a proposed treatment. The ethical requirement for *informed* medical decision-making is to ensure that patients are provided a fair and reasonable explanation of their medical condition and the risks and benefits of all treatment options, including the option of having no treatment (1). Although informed consent is often equated with a signed consent form, it is important to recognize that truly informed consent is not merely a signature on paper but the actual process of effective communication that results in patient understanding. Elements of informed consent include a discussion of: (a) the nature of the recommended treatment; (b) the risks associated with the treatment; (c) the risks associated with not having the treatment; (d) any available alternative treatments (including no treatment); and (e) the risks associated with the alternative treatments. A patient can give informed consent only if he has the sufficient and appropriate decision-making capacity to comprehend the nature of the illness and the risk–benefit analysis of the treatment plan (1).

General consent is the type of consent obtained in routine practice when a patient presents to the ED for care. In the case of a patient who willingly requests medical treatment, it is implied that he will consent to medical staff taking vital signs, performing basic diagnostic tests, and initiating noninvasive or minimally invasive treatment. These characteristics of general consent make it *not* equivalent to informed consent, since little—if any—discussion about the nature of the patient's illness or anticipated diagnostic and treatment plan occurs. Although the scope of general consent is broad and allows providers to perform a wide variety of actions on the patient's behalf, it is inadequate for procedures or tests that may be associated with a substantial risk of harm or injury.

When patients are unable to provide consent due to critical illness or the loss of their decision-making capacity, it is widely accepted that physicians can still treat patients under an emergency exception to consent. The emergency exception is narrowly structured and requires specific conditions to be met (2):

1. The patient must be unconscious or without capacity to make a decision, and no legally authorized representative who can act on behalf of the patient is available.
2. The patient must be in an emergency medical situation, such that delay of appropriate treatment to obtain consent would subject the patient to the risk of serious injury or death.
3. Under the same circumstances, a reasonable person would consent to the treatment.

Although these conditions permit an emergency exception to consent, consent is not completely waived. If the physician clearly knows that the patient would not have consented to the proposed life-saving treatment, such a treatment should not be administered. For example, patients near the end of life carry formal documentation that explicitly delineates their refusal of cardiopulmonary resuscitation, even if such a refusal results in their deaths. In such instances, unless there is evidence indicating the patient would have revoked their refusal or doubt regarding the validity of the signed documentation, the emergency physician should not initiate unwanted care.

Emergency consent is also only applicable until the patient recovers the capacity to make informed decisions or when a legally authorized representative becomes available. Physicians should take care to document in the medical record evidence supporting their clinical determination of an emergency medical situation necessitating an emergency exception to consent. Physicians also need to diligently note their determination of the patient's decision-making capacity, or lack thereof, when invoking the emergency exception. In situations where there is doubt as to whether the emergency exception applies, it is usually best to err on the side of treatment and to obtain the patient's or legally authorized representative's consent as early and reasonable as possible.

Refusal of Care

Conflict may arise when the patient refuses care or particular elements of treatment. Patients can and do refuse care, even when

that care is essential to preserve their life or health. In these not uncommon situations, providing unwanted treatment over the objection of a patient with sufficient decision-making capacity may render the physician liable for battery (3). Conversely, an impulsive or incompletely informed refusal leading to lack of treatment leaves the physician liable for negligence. Resolving this paradox in an emergency setting requires ethical skill.

A valid refusal requires sufficient decisional capacity on the part of the patient. A patient has decisional capacity when he is able to understand his medical condition, the treatment suggested, and the risks and benefits of each course of action (1). The patient must also be able to demonstrate that his decision derives from reasoning that is in keeping with his general goals and values. The criteria for refusal of care are consequently stricter than those for consent. Whereas general consent can be implied by a patient who arrives voluntarily to the ED, refusal of care *cannot* similarly be implied because the medical knowledge involved in an informed refusal is initially held only by the physician and not the patient. Therefore, whenever a patient refuses care, it is strongly recommended that the patient's decisional capacity be noted in the medical record, with special attention to the information that was specifically communicated and understood by the patient.

A great challenge for emergency physicians is to expertly assess decisional capacity to understand when a refusal is informed and when it is an impulsive gesture of a person who lacks decisional capacity due to severe psychiatric disease, intoxication, or overwhelming medical illness (4). For example, medical conditions such as hypoglycemia, encephalopathy, and hypoxemia can make patients impulsive, restless, angry, and antagonistic such that there may be confusion regarding their ability to reason. However, the mere presence of an intoxicant or medical illness—even a life-threatening one—does not necessarily imply that the patient lacks sufficient decisional capacity. The complexity of the information and decision, as well as the impact of the medical condition on the person's ability to process that information, should factor in assessing a patient's decisional capacity (1). The challenge then is to

ensure that the patient understands the risks and benefits of his options and can subsequently make a reasoned decision, even if it seems unreasonable to the healthcare provider. Patient refusal of care may apply to a specific test or treatment (e.g., a rectal examination or lumbar puncture), to any further care (e.g., a patient asking to leave during care or refusing admission to the hospital), or to a portion of the physician's plan of therapy (e.g., follow-up appointments, prescribed medications, or use of helmets). The critical and necessary skill of the emergency physician is to be able to differentiate refusal of care from a patient with decisional capacity from that of a patient who lacks such capacity as a result of serious illness or intoxication. It is not the responsibility of patients to prove they have decisional capacity; it is the responsibility of the physician to identify any impairment of such capacity.

When there is doubt regarding a patient's decisional capacity, medical care should always proceed to restore his capacity. In the meantime, protecting the patient from a dangerous decision is justifiable when sufficient uncertainty exists about whether the refusal represents a reasoned, durable decision. When treatment is delivered over a patient's expressed objection, the substantial impairment of the patient's decisional capacity should be clearly documented.

Patients who leave against medical advice should still be provided discharge instructions, follow-up information, and any medications that may help address the complaint or diagnosis. In addition, the discharge of patients from the ED against medical advice, even if amicable and mutually acceptable, should include a formal process (e.g., signing a leaving against medical advice form) in which the patient is made to understand the reasonable consequences of refusing to follow the discharge instructions. This information and its understanding by the patient should be fully documented (1).

CONSENT IN SPECIAL PATIENT POPULATIONS

Minors

There are special operational and ethical challenges associated with the care of minors. With rare exception, parents or legal guardians *must* consent for the care of a minor (5). The primary question that ED providers have regarding patients who are minors is when they can deliver care without parental consent or before parental consent. Should a teenager with a dislocated shoulder be made to wait until his parents arrive? Should a child with a laceration be put on hold? Should the ED physician respect the wishes of an adolescent who requests that his parents not be told of his visit? The answer to each question is predicated on a multitude of factors, including the maturity of the minor, the immediacy of harm from delay, the risk of the intervention, the type of illness, and whether the minor is emancipated.

There are several important exceptions to the requirement for prospective parental consent in the treatment of minors. First and foremost, in the presence of imminent harm wherein a delay of treatment poses a danger to the life or health of the minor, essential treatment should be provided. This provision is federally mandated under the Emergency Medical Treatment and Active Labor Act (EMTALA), which requires healthcare providers to provide stabilizing treatment to anyone who presents to an ED for medical care (6). Emergency physicians should be mindful that only care needed to preserve life and health should be administered and that simultaneous attempts at parental contact and consent remain necessary for continued care, even if the care is obviously needed.

If attempts to reach the minor's parents or appropriate surrogate are unsuccessful, the physician or social worker should notify state child protective services or the department of family services, who stand in the position of *parens patriae,* until the child can be released to the care of parents or surrogate caregivers.

Parental consent is also not required if the minor is legally emancipated. *Emancipated minors* have a different legal status than that of other minors, as defined by specific state law. In general, minors are considered emancipated and capable of making their own medical decisions when any one of the following conditions is met (7):

- Marital status: The minor is married, divorced, separated, or widowed.
- The nature of the minor's physical condition: The patient believes that she is pregnant or that he or she may be suffering from or have come into contact with any disease defined as a danger to public health (e.g., a sexually transmitted infection). Each state has differing requirements and age thresholds for these cases and ED providers should become familiar with the laws in their jurisdiction.
- Legal or financial status: The patient is either living on his own or is financially independent.
- The minor is a member of the armed forces.
- The minor is a parent.

In contrast to the emancipated minor, a special category of minor who may be able to offer *limited* consent for his own care is the *mature minor*. The mature minor (usually 14 years and older) is emotionally and intellectually sophisticated enough to be able to appreciate the nature of the illness along with the risks and benefits of proposed treatment (7). A mature minor's opinions and preferences should be taken into account when making treatment decisions (5). In some cases, a minor originally and incorrectly determined to be emancipated may meet standards for mature minor status. Because the mature minor may not be able to provide complete consent, including both the parents and mature minor in medical decisions is optimal.

In rare circumstances, a parent may refuse emergency treatment of a minor, even if such a refusal may cause severe injury or risk of death (5). In these cases all efforts must be made to ensure that communication between the providers and parent has been clear and adequate. This may require the involvement of social workers, chaplains, other family members, or other physicians to explore the parent's reasons for refusing treatment. When there is substantial risk to the minor in situations of parental refusal of consent, the minor should be taken into protective custody so that treatment can be given. For example, courts have held that physicians may administer life-saving blood products to a young child over the

objections of his or her Jehovah's Witness parents (3,8). The situation becomes more complicated when deciding if a mature minor's consent or refusal of essential care should be honored over a parent's objection. Courts have allowed mature minors to refuse life-saving treatment such as blood transfusions and chemotherapy over the objections of parents (8). Such cases often require emergency judicial intervention to clarify the physician's responsibility to the minor patient.

Psychiatric Patients

Patients with psychiatric disease who possess adequate decision-making capacity may refuse or consent to treatment just like any other patient. However, suicidal or homicidal patients who meet their state's statutory criteria for civil psychiatric commitment may not refuse treatment or leave the hospital against medical advice (9). Under the common law of all 50 states, emergency medical treatment of a suicidal patient may proceed against the patient's wishes for as long as it takes to stabilize the patient medically. This is in contrast to an initial limit of 72 to 96 hours (depending on the state) mental health providers have to evaluate and treat nonconsenting suicidal or homicidal patients (9). In cases wherein patients with psychiatric disease have been declared mentally incompetent by a court and placed under a conservatorship or guardianship, only the court-appointed conservator or guardian, and *not* the patient, can legally consent or refuse treatment. As noted above, in situations when the conservator or guardian is unavailable, emergency medical care for the patient should not be delayed.

Prisoners and Detainees

Patients who present under police custody can consent to or refuse medical care similar to any other nondetained patient. When a prisoner or detainee refuses treatment, the physician should follow the usual guidelines pertaining to the management of treatment refusals that apply to all patients, including an evaluation of the individual's decision-making capacity. Although patients in police

custody have the right to refuse medical treatment, they have no legal right to choose where they are incarcerated. A prisoner or detainee who has refused treatment but who is suffering from a potentially significant medical condition may still be admitted to a hospital's jail ward against his wishes at the request of law enforcement authorities.

Prisoners and detainees have a legal right to medical care under federal law, and the failure of authorities to provide such care may be regarded by the courts as a violation of the prisoners' civil rights (10). It is in this context that police and prison officials bring prisoners and detainees to the ED for treatment and "medical clearance" evaluations. Emergency physicians should remember that many prisoners and detainees suffer from poorly controlled or untreated conditions, including polysubstance abuse, that are associated with a variety of health risks that may go undetected in a detention facility staffed by personnel who lack medical training. Depending on the clinical circumstances, it may be wise to consider hospital admission if there is a concern that a prisoner or detainee may require a level of treatment or monitoring that is otherwise unavailable in jail or prison.

Intoxicated Patients

Emergency physicians are often confronted with patients under the influence of alcohol or drugs who refuse medical care. Physicians can make a determination of a patient's sobriety or intoxication based on clinical examination alone, and a blood alcohol level is not required. Although an intoxicated patient does not completely lack decision-making capacity, the threshold to override the patient's refusal is lower. An intoxicated patient cannot refuse emergency medical treatment or sign out against medical advice without exhibiting the ability to fully comprehend the risks associated with refusing treatment (10). In such cases the emergency physician would be prudent to carefully document his reasons for overriding the intoxicated patient's wishes.

Restraints

Violent or combative patients who present an immediate risk to themselves or others in the ED may require the use of physical or chemical restraints. Courts have generally deferred to the professional judgment of a physician to determine when restraints are necessary (11). Physicians, however, must adhere to federal regulations governing the use of restraints and document the clinical need for restraints. Federal regulations require that orders for restraints: (a) cannot be written as a standing or on an as-needed basis; (b) be implemented in the least restrictive manner; (c) are in accordance with safe and appropriate restraining techniques; and (d) end at the earliest possible time (12). Restraints should only be used to ensure the safety of patients and providers, and never punitively when a patient is disruptive or noncompliant. Providers must understand that the inappropriate use of restraints—both *actual* (wrist and ankle straps or administration of medication) or *apparent* (verbal threats, presence of guards, being placed in a locked examination room)—can represent false imprisonment and subject the provider to liability. Providers should therefore pay special attention to documenting in the medical record reasons for the use of restraints. Finally, as restrained patients are unable to care for themselves and may continue to be agitated, care should be taken by staff to monitor them for safety. Most centers remove physical restraints and transition to chemical restraints in the form of sedative medications as early as possible.

END OF LIFE ISSUES

"Do Not Resuscitate" Orders, Advance Directives, and Living Wills

Death and dying are deeply personal and emotional matters, and many patients near the end of life may wish to forgo extraordinary life-sustaining measures. By enacting a "do not resuscitate" (DNR) order, advance directive, or living will, patients allow their wishes to be known when they are unable to communicate them.

Unfortunately, there exists much confusion about DNR orders, advance directives, and living wills.

Advance directives and living wills are broad documents that outline the general end-of-life wishes of the patient. These documents can be established by patients and do not always contain specific provisions about withholding cardiopulmonary resuscitation. As a result, unless a living will or advance directive contains DNR clauses, they may not be helpful in the emergency setting. DNR orders, in contrast, specifically address a patient's wishes with regard to cardiopulmonary resuscitation and it is an order written by a physician. Many states employ specific and standardized forms that must be used to establish a valid DNR order. Hospitals are also required to have mechanisms in place for patients to express therapy-limiting decisions and to ensure that this information is available to healthcare providers (13).

When a DNR order, advance directive, or living will accompanies a patient without decisional capacity to the hospital, in theory, no proxy decision maker may be necessary since the document was designed to speak for the patient. In cases when there is no uncertainty regarding the patient's medical condition and wishes, the DNR order, advance directive, or living will should rightfully be honored. Problems can arise when uncertainty exists. When the designated surrogate decision maker, for example, disagrees with a plan to limit treatment, most emergency physicians would properly deliver care until the incongruity can be sorted out. Similarly, a patient who resides in one state and has a specific, valid advance directive may find himself in need of emergency medical care while vacationing in a neighboring state, in which his advance directive may not be legally recognized. While some emergency physicians would consider the intent of the legally invalid advance directive and limit care in accordance with the document, others may feel compelled to render care until this legal dilemma can be formally resolved. The problem of rapidly determining the validity of a variety of legal documents regarding end-of-life preferences in an emergency setting will not be resolved until an easily interpretable,

portable, and widely available form (paper or electronic) that is recognizable across all healthcare settings becomes available (14).

Another problem of DNR orders, advance directives, and living wills is their applicability in unforeseen circumstances. For example, a cancer patient who with his oncologist enacts a DNR order to forgo cardiopulmonary resuscitation and intubation in anticipation of his advancing disease, poses significant ethical and legal problems when he unexpectedly presents to the emergency room in respiratory distress due to anaphylaxis from an accidental food allergy. While the patient's DNR order specifically indicates his desire to not be intubated, it was created under the rubric of his underlying cancer and unlikely accounted for a scenario such as anaphylaxis from a food allergy. The proper question from an ethical view is whether there is clear, sufficient, and valid evidence of what the patient would want for this specific circumstance. If there is doubt, resuscitative attempts should proceed. Emergency physicians can take comfort in knowing that there is no legal or ethical distinction between withdrawing unwanted care and not initiating care (15). Undesired interventions can be withdrawn once the proper information becomes available regarding the patient's end-of-life wishes. As additional information is gained about the medical condition and the patient's enduring wishes, goals, and values, ongoing treatment can then be modified. Relevant information must be incorporated into the decision-making process and shared with the patient and family to achieve the best possible resolution.

Surrogate Decision Makers

The Uniform Health-Care Decisions Act permits an individual to appoint a legally authorized surrogate for healthcare decisions (13). The surrogate may then authorize medical treatment and provide information regarding patient wishes if the patient loses decisional capacity. As is often the case in the ED, the surrogate may not be available when the patient requires emergent medical treatment. Relying on available family members who are not the legally

authorized decision maker may be problematic, as these family members and the legally authorized surrogate may disagree about treatment decisions. The emergency physician should inquire whether the patient has a legally designated decision maker, clarify roles and relationships of those expressing opinions, and document the input received. If the official surrogate is unavailable or if the emergency physician identifies uncertainty because of sudden or unusual medical circumstances, it is appropriate to deliver care so that decision-making can be later clarified. Alternatively, if an authorized surrogate requests that treatment be withdrawn, this desire can be honored when there is no uncertainty or conflict, and when the decision would be concordant with the patient's understood wishes. It is important to note that in the absence of any established designated surrogate, the following persons, in decreasing order of priority, may lawfully consent to treatment on the patient's behalf: the patient's spouse; adult child; parent; brother or sister; or relative by blood or marriage.

COMMUNICATION, PRIVACY, AND CONFIDENTIALITY

Patient privacy—the physical and psychological condition of appropriate separation from others—is deserved by patients, is a challenge for caregivers, and is sometimes impossible in a busy, crowded ED (16). The ED is a unique environment in that there are no limits on the number of patients requiring immediate medical attention. Care is routinely provided in hallways when critical medical tasks take priority over important privacy needs. Privacy must also be sacrificed for patient safety. A highly private environment, for example, does not allow for visual monitoring by nurses and doctors and may impair medical care. Though it may be easy for many providers to forgo privacy for the sake of providing timely treatment to critically ill patients, the better position may be to attempt to maintain the value of privacy despite the ED's challenging conditions. In the clinical environment, this may require softer voices on the part of caregivers when discussing patients during shift transitions. Physicians can also be mindful of keeping

curtains fully drawn during physical examinations. Though these issues may seem trivial when lives are at stake, they are meaningful ways to respect patients and demonstrate high ideals of the profession.

Just as providers should aim for as much patient privacy as possible in the emergency care setting, patient confidentiality must also be ensured. Patient information should not be seen by anyone other than those individuals with a duty to care for the patient. The Health Insurance Portability and Accountability Act (HIPAA) provides specific instructions regulating and protecting the confidentiality of a patient's medical information, and must be followed by all who might encounter such information, including doctors, nurses, secretaries, clerks, pharmacists, allied providers, insurance agencies, health plans, and businesses with transactional relationships with healthcare systems (17). The increased rigor applied to the sharing of patient information can sometimes result in higher costs and burdens on healthcare providers in their ability to use and share full medical information when treating patients in a timely and efficient manner. Nevertheless, it remains prudent to remind all who work in the ED that they have knowledge of the patient's condition only because of their privileged position as a healthcare worker and that information should be shared only for the medical treatment of the patient.

The confidentiality of information provided by minors during their care in the ED is a common area of concern (5). Although it is widely known that adolescent patients are more candid when they are assured confidentiality, ED providers need to exercise caution in overpromising confidentiality when HIPAA allows parents of minors to access medical records. Still, ED providers should be aware that HIPAA does permit a licensed healthcare professional to deny parental access to medical records under certain circumstances, such as when the provider believes that the access requested is reasonably likely to endanger the life or physical safety of the patient or another person (18).

TRUTH TELLING AND RELATIONSHIP BUILDING

Though it may initially seem simplistic to discuss how to tell patients the truth, in practice, truth telling is not always so easy in an emergency setting. The emergency physician and the patient often do not have a pre-existing relationship, do not know each other well, and may not share a mutual trust. In the busy ED, it is difficult to spend sufficient time with patients and families such that a productive therapeutic relationship can be established. It therefore becomes crucial that emergency physicians are mindful of the first impressions they make with patients and their families. The truthful and trusting relationship begins with proper eye contact, prudent physical contact such as a handshake, attentive body language, and active listening. Elements of this relationship must be established quickly in the ED. Although a busy physician may feel there is little time to establish this connection, these elements make up the essential core around which a satisfactory relationship is established.

These aspects of truth telling and relationship building are important under all circumstances but more so when upsetting results of diagnostic tests need to be communicated or when bad news must be delivered. Perhaps more important, the trusting alliance may need to be established at the same time that information regarding medical errors are disclosed. Many professional societies, patient safety experts, and standard practice guidelines recommend disclosure (19). There are many reasons favoring the disclosure of harmful errors to patients. Disclosure supports truth telling, patient autonomy and informed decision-making, and is consistent with patients' preferences (20). Patients want to know about errors even when the harm is minor, and expect a full explanation and an apology (20). Patients also seek acknowledgement of the pain and suffering that was caused by the error, along with reassurance that recurrences will be prevented. In addition, disclosure can facilitate the principle of justice, as patients cannot seek compensation for medical injuries they did not know were caused by a medical error. Finally, disclosing errors to patients

promotes patient safety, as it enables the critical appraisal of the conditions leading to errors and the development of interventions to prevent recurrences.

The patient and family must sense honesty in the language, openness in the posture, and integrity in the practice. Patients can often tolerate mistakes, but they will not tolerate physicians who do not care. To complicate matters, many patients at the outset are suspicious, untrusting, demanding, or even violent during their ED visit, making the act of error disclosure even more risky. Information regarding errors must be explained to the patient in the proper context, even though the physician's natural instinct may be to cover up mistakes. This is a precarious maneuver both professionally and legally, especially if the patient or family later discovers the error. Conversely, if the patient is unable or unwilling to engage in a conversation, attempts to divulge a medical error should be noted on the record, and plans for later communication should be made.

Historically, physicians were advised not to disclose errors to patients by risk managers and lawyers who worried that offering an apology or an admission of fault would precipitate malpractice suits. Recent research suggests this assumption may be unfounded (19). Many patients who file medical malpractice claims do so because they believe that disclosure was absent or inadequate and see legal action as their only option for finding out what happened. In addition, healthcare organizations that have adopted robust disclosure programs are reporting favorable outcomes (21). The University of Michigan, which couples disclosure with offers of financial compensation for harmful errors, reported significant reductions in the number of claims filed, litigation costs, and time to resolution (21). In addition, 35 states and the District of Columbia have adopted laws making medical apology inadmissible as a statement of fault, with some states even requiring the disclosure of serious unanticipated outcomes to patients (22). These developments have led many risk managers and malpractice insurers to strongly advocate for disclosure.

When disclosing a harmful medical error to a patient and his or her family, the provider should focus the conversation around the needs of the patient (19,20). The provider needs to present information in a fashion that the patient and family can comprehend. Patients should be told the facts surrounding the event, what steps have been taken to address any medical repercussions, and plans to prevent recurrences. It is also important to explain to the patient and family that they will not incur additional financial costs due to the medical error. Finally, the provider should apologize and express regret for the error. It takes expertise to know how to disclose errors and communicate properly, and emergency physicians should aim to master these special and important skills.

USE OF THE NEWLY DEAD FOR EDUCATION

Emergency physicians must develop and maintain expertise in a wide array of procedural skills, some of which are rarely performed. Many training programs in the past taught procedures on patients who were pronounced dead in the ED (23). The tactile accuracy, accessible teaching opportunity, and situational realism enabled the development of expertise for young physicians who would soon have full responsibility to perform the life-saving skill on future patients. Because it was believed that there was a broad societal obligation to support the training of physicians that could not be easily obtained in another way, the teaching of procedures performed on the newly deceased was conducted. This practice, however, was fraught with ethical controversy and complications mainly because the teaching was often performed without the awareness or permission of the family. Some of the debate surrounding procedural teaching on the recently deceased focused on the type of procedure being taught. Needle insertion, incision, and physical inspection were considered variably acceptable, based primarily on the degree of invasiveness. Endotracheal intubation, for example, might be considered relatively more acceptable, because it was not disfiguring, whereas cricothyrotomy might be

deemed unacceptable. Although there may be some merit to such distinctions, the delineation has not been fully satisfactory.

The answer to this dilemma is rooted in the core ethical obligation of the profession. Physicians must maintain the trust of the individual and the public. The transformation of a person from a patient to a teaching tool seems contrary to the requirement to maintain trust. Therefore, family permission is always encouraged before teaching invasive procedures (23).

PROFESSIONAL LIABILITY

Despite the best intentions of healthcare providers and institutions, adverse events and medical errors occur relatively frequently. Approximately 400,000 adverse drug events and 100,000 patient deaths are estimated to occur annually in American hospitals and clinics, figures that may be conservative given the prevalence of underreporting (24). The ED is one of the most error-prone settings in healthcare (25). The ED practice environment is often chaotic, unpredictable, and potentially hazardous. Emergency physicians make critical medical decisions with incomplete information and under time pressure, and confront a wide range of undifferentiated medical problems. For these reasons, emergency physicians should have at least a basic understanding of professional liability.

Elements of Professional Liability

In a professional liability action against an emergency physician, the plaintiff must prove that (1) the emergency physician owed the patient a duty of reasonable care; (2) the physician breached that duty; (3) there is a causal connection between the physician's conduct and the resulting injury to the plaintiff; and (4) there is an actual injury to the patient (26).

The first two elements of duty and breach of that duty constitute negligence. Legally, negligence is defined as the "failure to use such care as a reasonably prudent and careful person would use under similar circumstances; it is the doing of some act which a person of ordinary prudence would not have done under similar

circumstances or failure to do what a person of ordinary prudence would have done under similar circumstances" (27). Negligence consists of a breach of the duty to adhere to a concept known as the "standard of care." The traditional measure of the standard of care for physicians requires that a physician exercise the "average degree of skill, care, and diligence exercised by members of the same profession, practicing in the same or similar locality in light of the present state of medical and surgical science" (28). It is important to note that the "locality" rule has since expanded into a national standard as a result of advances in modern medical education and training, medical journals that reach a national audience, and continuing medical education courses at the national level.

The courts depend on expert medical testimony to assist in determining whether a physician's conduct was negligent and whether the alleged negligent conduct was the proximate cause of the patient's injury. For the court to find a causal connection, the patient's injury must be a foreseeable consequence of the physician's conduct. If the patient's injury is not causally related to the physician's alleged negligent conduct, there is no professional liability. Unlike the causation element in a product liability case, in which it is usually clear that a particular product caused a particular injury, the causation element of a professional liability action in medical cases is extremely complex and strenuously contested because bad outcomes frequently accompany serious disease processes in the absence of negligence.

Failure to Diagnose

Most professional liability actions against emergency physicians arise under allegations of a failure to diagnose a serious emergency medical condition in a timely manner. Four important factors have been identified as being responsible for breakdowns in the diagnostic process: (1) failure to order an appropriate diagnostic test; (2) failure to create a proper follow-up plan; (3) failure to obtain an adequate history or to perform an adequate physical examination; and (4) incorrect interpretation of a diagnostic test

(29). Emergency physicians are the most frequently involved clinicians (52%) in diagnostic errors, followed by primary care physicians (28%), surgeons (20%), radiologists (16%), and nurses (10%). Residents are involved in 56% of cases (25). These data highlight the high stakes and complicated nature of emergency medicine of which even seasoned emergency physicians should always be mindful.

Hindsight Bias in Professional Liability Actions

In making allegations of professional negligence, plaintiffs' attorneys are aided by a phenomenon, first described by cognitive psychologists, known as hindsight bias. Hindsight bias describes how knowledge of a particular adverse outcome may bias an observer's perspective of a complex series of events such that a person who has knowledge of the adverse event cannot maintain an unbiased view of the reasons for the adverse event. Hindsight bias creates a "knew it all along" effect in which observers of past events exaggerate what other people should have been able to anticipate prospectively (30). However elusive the patient's diagnosis on initial presentation, the diagnosis appears deceptively and obviously simple to those with knowledge of the adverse event acquired in hindsight. Jurors are prohibited from using knowledge based on hindsight in their deliberations and are so instructed in their jury instructions. Unfortunately, as a result of the hindsight bias effect inherent in cases of delayed diagnoses, anyone with knowledge of the adverse outcome will know exactly what definitive diagnostic test or treatment the emergency physician could have ordered, and improperly impute that knowledge should have been apparent to the physician. It is a small step for jurors armed with hindsight to proceed to the erroneous conclusion that a physician's failure to order a particular test or treatment course constituted negligence and hold the physician liable to the patient.

Common Pitfalls

- Failure to assess and document the decisional capacity of patients who refuse care.
- When encountering an advance directive or living will, failure to ask, “does this represent clear, consistent, and valid evidence of what the patient would want for this specific circumstance?” If there is an affirmative response, the directive should be honored.
- Failure to document the provision of an explanation of medical risks to patients leaving against medical advice, as well as failure to give them discharge instructions, medications, and follow-up information as appropriate.
- Failure to document patient’s expressed wishes on the medical record.
- Failure to document justification for the use of physical or chemical restraints.

ACKNOWLEDGMENT

The authors thank and recognize Howard A. Peth, Jr. for his prior contribution to and the integration of parts of Chapter 383: Legal Issues from the 5th edition into this current edition.

CHAPTER 382

Regulatory Issues

Larry D. Weiss and Jorge A. Martinez

Ever increasingly, state and federal regulations control the practice of medicine in the United States. Each state has agencies which conduct activities such as licensure, provider and institutional compliance, and disciplinary actions. In addition, Congress and federal agencies including the Drug Enforcement Agency, the Center for Medicare and Medicaid Services, and the Federal Trade Commission regulate, administer, and monitor the practice of medicine throughout the United States and oversee reimbursement for healthcare services.

THE AFFORDABLE CARE ACT

The Patient Protection and Affordable Care Act (ACA), which became effective in 2010, represents an effort by Congress and the Obama administration to significantly reform the health insurance industry in the United States (1). Congress intended these reforms to (1) provide near universal health insurance coverage, (2) improve the quality of care, and (3) lower the cost of care. Unlike many European countries which have a centrally controlled single payor system, the ACA provided a complex system of controls to reform the myriad payor systems existing in the United States. Thus, the ACA reforms payor systems in the United States while preserving the basic underlying insurance systems.

The ACA intervenes in more than 25 significant ways to improve the availability of private health insurance. It dramatically expands the government funded Medicaid insurance system for poor

patients. For the first time, Medicaid will provide coverage for all poor patients with a household income of less than 133% of the federal poverty level. Even though the US Supreme Court mostly upheld the constitutionality of the ACA in a June 2012 decision, it declared that Congress could not coerce state governments to expand Medicaid in their respective states (2). Therefore, states may independently decide whether to participate in Medicaid expansion. Many commentators predict up to 20 states may elect not to initially participate when Medicaid expands on January 1, 2014.

To capture patients who earn more than 133% of the federal poverty level, but still may lack the funds to purchase traditional health insurance products, the ACA provides for the creation of state heath benefit exchanges whereby patients may select lower cost "qualified health plans" which must include a list of "essential health benefits." Finally, the ACA provides for near universal health insurance coverage by requiring an individual "mandate" to purchase insurance by January 1, 2014. Failure to purchase insurance will result in a fine, payable on a sliding scale according to income. Those who would have to spend more than 8% of their adjusted gross income on health insurance would not have to pay a fine.

The ACA hopes to improve the quality of care and lower the cost of care primarily through the operation of Accountable Care Organizations (ACOs). A description of the functioning of ACOs lies beyond the scope of this chapter. It suffices to say that ACOs will establish quality and cost goals. If the ACO meets these goals, providers will receive cash payments through "gainsharing" rewards from the Medicare and Medicaid programs. If they fail to meet these goals, then providers must pay a penalty.

A large title of the ACA deals with workforce issues, and will have a largely negative impact on emergency medicine. This section of the ACA provides funds for the training of physician extenders and primary care physicians. However, the ACA defines primary care as general internal medicine, family practice, and general pediatrics. The ACA provides for an immediate redistribution of residency slots toward the three primary care specialties. Initially, these

redistributed slots will come from two sources, (1) slots that were unfilled for 3 years, and (2) slots from closed hospitals. Thereafter, Medicare graduate medical education funds will provide for new primary care residency programs and the expansion of existing primary care residencies.

After the ACA went into effect in 2010, the various federal departments and agencies began writing regulations required by the ACA. Most of these regulations will come from the Center for Medicare and Medicaid Services (CMS). These regulations will deal with payment, quality control, ACOs, tax issues, medical education and training, and a host of other related issues. On the one hand, the ACA banned the use of "prior authorization" requirements by insurance companies for emergency department (ED) visits, and banned the use of higher copayments for ED visits, but on the other hand, a recent CMS Regulation allows insurance companies to choose a low level of reimbursement for emergency medicine providers (3). Emergency medicine advocates have an opportunity to influence the regulatory process, and a number of emergency medicine societies banded together to form lobbying groups (4).

Another area of potential difficulty in the regulatory process concerns the regulation of ACOs. In most communities, an ACO will include at least one hospital and many physicians and other providers. When the ACO contracts with insurance companies, it will have to negotiate price. This will create antitrust risk for physicians and other providers, as competitors may not discuss price, and definitely may not enter into agreements on price. Government expects all physicians in a market area to act as competitors. Two exceptions exist to this general rule, (1) physicians who practice in a group and use the same taxpayer identification number, and (2) employees. Even if an ACO includes only one emergency physician group, government investigators could consider these emergency physicians as competitors of other physicians in the ACO, such as primary care physicians, anesthesiologists, or any other physician who performs a service similar to any ED service.

Therefore if these physicians bargain for price with an insurance company, a government inspector could decide that these physicians engaged in price fixing, usually a criminal violation of the Sherman Antitrust Act. To avoid such potential liability, the ACO would have to evolve into a truly integrated delivery system, or the physicians would have to become employees of the hospital. Of these two options, becoming an employee would be the only sure way to avoid antitrust liability. For these reasons, unless physicians receive some regulatory antitrust relief, the development of ACOs may lead many physicians to become employees. In emergency medicine, this could threaten the viability of independent democratic groups. It could also threaten the viability of large contract management groups.

Advocacy efforts on behalf of emergency medicine should focus on influencing the regulatory process in the following areas: modification of regulations controlling payment for emergency services, antitrust relief to facilitate the development of ACOs, and modification of workforce policies that will restrict future training positions in emergency medicine. The ACA will create profound and long-lasting changes in the practice of medicine. Many of these changes will have a negative impact on emergency medicine, but many of these changes may be mitigated through appropriate advocacy during the regulatory process.

THE EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT

Congress enacted the Emergency Medical Treatment and Active Labor Act (EMTALA) in 1986 to prevent financial discrimination in hospital EDs. Congress was concerned about economic dumping of uninsured patients from hospital EDs. The purpose of the Act was to prevent discrimination in the evaluation and treatment of ED patients in any form. The crux of the statute is to ensure similar and nondiscriminatory evaluation and treatment of all individuals who present to an ED, whether insured or not.

Under EMTALA, if an individual comes to an ED and a request is made on their behalf for examination or treatment, then they must

receive (1) an appropriate medical screening examination (AMSE), (2) stabilization of their emergency medical condition, and (3) appropriate transfer when indicated (5). EMTALA does not define what constitutes an “appropriate medical screening examination,” but does declare that the examination must include ancillary services routinely available to determine whether an emergency medical condition exists (6). Federal courts concluded that an AMSE requires hospitals and physicians to provide an examination comparable to similarly situated patients (7).

EMTALA provides that any individual found to have an emergency medical condition (EMC), including active labor, must be stabilized before they may be transferred. Stabilization means “to assure, within reasonable medical probability, that no material deterioration of the condition is likely to result from or occur during the transfer” (8). EMTALA defines transfer as “the movement (including the discharge) of an individual outside a hospital’s facilities at the direction of any person employed by (or affiliated or associated, directly or indirectly, with) the hospital . . . It does not include such movement of an individual who has been declared dead or leaves the facility without the permission of any such person (9). EMTALA allows a physician to transfer an unstable patient to another hospital, if the medical benefits of the transfer outweigh the risks (10). Additionally, a competent patient or surrogate decision maker may also request a transfer. In either situation the transferring hospital must provide all treatment within its capabilities; must obtain the consent of the patient or surrogate for transfer; must contact the receiving hospital and secure approval for the transfer; must document that the receiving hospital accepted the patient; must send all relevant medical records, and must assure that the patient is transferred by qualified personnel with adequate equipment to complete the transfer (11).

Hospitals may not delay AMSEs to inquire about payment for services or insurance coverage (12). Furthermore, hospitals with specialized capabilities, or regional referral hospitals in rural areas, may not refuse appropriate transfers, if they have available beds and staffing (13). EMTALA obligations end once a patient with an EMC

is admitted in good faith to a hospital as an inpatient (14). Plaintiffs may only file suit against a hospital, for an alleged EMTALA violation, not the physician (15). Hospitals and physicians may be fined up to $50,000 per occurrence and be excluded from Medicare for flagrant or repeated violations. Hospitals have the right to sue physicians in indemnification to recover the cost of the fines.

CMS wrote a series of regulations that interpret the EMTALA statute and guide its implementation. An individual has "come to the ED" when he arrives on hospital property (16). Hospital property is defined as (1) the area immediately adjacent to the main building, and (2) other areas owned and operated by the hospital within a 250-yard radius of the main building (16). An off-campus facility qualifies as a dedicated ED if (1) it has an ED license, (2) it holds itself out to the public as providing emergency care, or (3) during the preceding year, one-third of outpatient visits were for emergency medical conditions (16). EMTALA does not apply to inpatients, unless the hospital admits the patient in bad faith to avoid providing stabilizing treatment. Nor does it apply to scheduled outpatient visits in a hospital clinic (16). Finally, hospitals must maintain an on-call list of physicians on its medical staff based on the needs of its patients, resources available, and availability of on-call physicians. They must have written policies and procedures to respond to situations where a particular specialty is not available or the on-call physician cannot respond because of circumstances beyond the physician's control. They must also provide that emergency services are available to meet the needs of patients if the hospital elects to permit on-call physicians to schedule elective surgery or cover concurrent on-call duties (16).

HIPAA AND HITECH

Access to a patient's health information (HI) is essential to provide appropriate and comprehensive medical care. During treatment, a patient's HI is exposed to numerous healthcare providers, support personnel, and payers. A major concern is that persons not involved in a patient's medical care may gain unauthorized access or

exposure to HI inadvertently or intentionally and divulge it to third parties.

In response Congress enacted the Health Insurance Portability and Accountability Act (HIPAA) in 1996. The intent of the Act was to guarantee that individuals retain access and control of their HI and to ensure that healthcare providers treat HI in a confidential manner. HIPAA applies to all HI, whether communicated, stored, or transmitted in oral, written, or electronic form. This includes oral conversations, telephone calls, faxes, letters, e-mails, text messaging, computer drives, and data centers.

The principal part of HIPAA affecting the ED is the *Administrative Simplification* section, 45 CFR Parts 160, 162, 164 (1996). It contains privacy and security regulations which (1) describes how an individual's HI may be used and disclosed, (2) incorporates privacy and security standards to safeguard the integrity, confidentiality, and availability of HI, and (3) provides specific patient rights concerning their HI; and creates national standards for electronic healthcare transactions, including data and transaction formats and specific code sets for diagnosis, procedures, and medications. The law compels privacy and security measures to prevent unauthorized disclosure, access, alteration, destruction, or release of HI. It also establishes unique identifiers for providers and third-party payers, and details sanctions for violations.

A covered entity (CE) under HIPAA may use protected health information (PHI) for treatment, payment, and healthcare operations (17). CEs are not required to obtain an individual's authorization to use PHI. HIPAA requires a CE to obtain an individual's written authorization before it may disclose PHI outside of the CE (18). Exceptions allowing PHI to be disclosed without prior authorization involve public health matters.

On February 13, 2009, Congress passed the Health Information Technology for Economic and Clinical Health Act (HITECH). Through HITECH Congress instituted incentives for the meaningful use of electronic health records (EHRs). It also expanded HIPAA's privacy and security provisions directly to business associates, revised civil monetary penalties for violations, and mandated

accountings for disclosures made for payment, treatment, or healthcare operations via an EHR.

Civil penalties are tiered based on severity of the violations. The minimum fine is $100; the maximum fine is $50,000 per individual violation. Maximum civil penalties for multiple violations range from $25,000 to $1.5 million per year (19). Moreover, criminal sanctions may be imposed against CEs and persons within the CE. If the PHI is obtained or disclosed without authorization, the fine is $50,000 and/or incarceration for up to 1 year.

Common Pitfalls

- The Affordable Care Act and its Regulations contains many pitfalls for the specialty of emergency medicine including limitations on reimbursement for emergency services, antitrust risks for physicians in ACOs, and future financial limitations on emergency medicine training programs.
- Failure to provide an AMSE for every individual who seeks care in an ED.
- Failure to provide stabilizing treatment to the maximum capability of the hospital before transferring patients.
- Failure to obtain proper authorization prior to the release of protected health information.
- Failure to establish administrative, physical, and technical safeguards to protect the privacy and integrity of health information.

CHAPTER 383

Interpersonal Violence

Abigail Hankin-Wei and Debra Houry

The term *interpersonal violence* implies violence between two people with some relationship (partner, family, acquaintance, gang-related, patient, etc.). This chapter focuses specifically on intimate partner violence (IPV) and provider exposure to violence in the emergency department (ED) setting. Specific information on sexual assault (Chapter 135); trauma in older adults (Chapter 53); and pediatric physical and sexual abuse and neglect (Chapter 290) can be found elsewhere in this textbook.

Also known as *domestic violence, spousal abuse,* or *battering,* IPV can present in the form of physical, sexual, or psychological abuse, or a combination of multiple forms of abuse—perpetrated against a former or current partner. A recent population-based study reported that 29% of women have experienced physical, sexual, or psychological IPV in their lifetime (1). IPV results in nearly 2 million injuries and 1,300 deaths nationwide every year (1).

The incidence of IPV victimization within the past 12 months among female ED patients has been reported to range from 11% to 20% (2–4). Many victims of IPV seek medical care for their injuries in EDs (2,5,6), while others present to EDs for treatment of complaints related to IPV, such as depression, posttraumatic stress disorder, substance abuse or complications of pregnancy secondary to abuse (7,8). In many cases, the ED is the primary access to health care for these patients. The lifetime prevalence of IPV exposure in ED patients has been estimated to be as high as 50% (9). In a recent report, the Institute of Medicine issued a recommendation that screening and counseling for IPV for all women, as part of standard

preventative services, noting that such screening should be done in a "culturally sensitive and supportive manner" (10).

Violence within the ED is a problem that is underreported. The ED lends itself to promotion of a violent environment as a result of the volume of sick patients, long wait times, availability of drugs, 24-hour accessibility, and potentially violent psychiatric patients awaiting medical clearance. In one survey of emergency physicians in Michigan, 74.9% of those surveyed reported a verbal threat in the prior 12 months, while 28.1% reported that they had been physically assaulted in the workplace in the same interval. Among physicians, female gender and fewer years in practice were significantly associated with risk of assault (11).

Multiple studies have shown that, while workplace violence is common, victims often suffer in silence, with severe consequences for their mental health. Gates et al. (12) reported that 65% of assaulted ED workers did not report the assault to hospital authorities. Kowalenko et al. (6) reported that 81% of emergency physicians were occasionally fearful of workplace violence and 9% were frequently fearful. In one study, 42% of emergency physicians sought various forms of protection including obtaining a weapon to protect their personal safety (11).

The American College of Emergency Physicians (ACEP) developed a policy statement on protection from physical violence in the ED (5). ACEP stated that hospitals must ensure the provision of adequate security personnel, coordination of hospital security with local law enforcement agencies, the development of written protocols for violent situations in the ED, and education of staff on violent situations.

CLINICAL PRESENTATION

Intimate Partner Violence

IPV risk crosses all societal categories. However, studies have shown that risk of IPV victimization increases among patients with poor mental health (including depression and increased suicide risk), poor physical health and concurrent medical comorbidities, low

income and low level of educational attainment, as well as race/ethnicity (although differences in ethnicity disappear when socioeconomic status is controlled for) (7,13,14).

IPV victims may present to the ED for treatment of an injury from IPV, evaluation of a chief complaint exacerbated by their situation (headache, anxiety, chronic pain), evaluation of nonspecific general medical complaints such as mental illness, substance use, or poorly controlled comorbid conditions, or a history of IPV that is elucidated via standard screening. Common presentations of battered women are listed in Table 383.1.

TABLE 383.1
Common Presentations of Women Experiencing Intimate Partner Violence

Trauma to the face, neck, or throat
Trauma to the chest, breast, abdomen, or genitals
Bilateral or "pattern" injuries
Sexual assault
Chronic pain
Multiple injuries in various stages of healing
Extent or type of injury inconsistent with patient's explanation
Repeated use of the ED
Psychological or emotional complaints
Evidence of alcohol or drug abuse
Suicidal ideation or behavior

Violence in the ED

Patient-based factors that predict agitation and risk for violent behavior include substance abuse and intoxication, explosive or unpredictable anger, intimidating behavior, hostile and threatening verbal behavior, a history of self-harm, and resistance to medical care (15). At a facility level, interventions that reduce risk of violence in the ED include the use of metal detectors, security staff presence in the ED, and structural changes including panic buttons,

improved lighting and visibility, and surveillance camera monitoring of the entire department (16).

DIFFERENTIAL DIAGNOSIS

IPV should be considered in the differential diagnosis of every ED patient, particularly in patients with nonspecific symptoms, or complaints associated with substance abuse or mental health. Patients with recurrent visits to the ED for vague, somatic complaints should be asked about IPV, as this may be the underlying etiology. Patients with traumatic injuries should be questioned specifically about how the injury occurred, especially if the physical examination findings are inconsistent with the stated mechanism. Without asking specifically about IPV, the diagnosis of abuse may not be made in these cases (17). It is important to ask about and identify IPV, as women who disclose IPV are at risk for incurring future injury (3).

With respect to the violent patient in the ED, it is important that clinicians evaluate for medical causes of the patient's agitation after securing patient and staff safety. Metabolic abnormalities, infection, and trauma are life-threatening causes of altered mental status and agitation that must be ruled out. Table 383.2 lists key diagnoses to be considered.

TABLE 383.2
Organic Causes of Violent Behavior

Drug intoxication: PCP, LSD, cocaine, barbiturates, amphetamines, and alcohol
Trauma: closed-head injury, subdural hematoma, tension pneumothorax
Infection: AIDS, encephalitis, meningitis
Metabolic: hypoglycemia, thyroid storm, renal or liver failure, adrenal crisis, ketoacidosis, hypoxia, hypothermia, hyperthermia, and vitamin deficiency
Neurologic: tumors, epilepsy, cerebrovascular accidents, infections
Iatrogenic: medication-induced delirium

ED EVALUATION

Intimate Partner Violence

Studies have reported that patients will not disclose IPV unless prompted by a health provider (17). Thus, ED patients should be routinely screened for IPV. This can be done as part of the nurse's triage intake or during the physician's history and physical examination. Questioning should always be carried out in private and with a nonjudgmental manner.

Physicians have several specific areas of responsibility in the evaluation and management of patients who are experiencing IPV: to screen for IPV; to provide medical treatment; to document findings and utterances; to facilitate appropriate referrals and follow-up; and to ensure the patient's safety.

Patients thought to have injuries resulting from IPV should be interviewed in a quiet, secure area of the ED without their partner, family, or friends present. Patients should be asked in private whether they want their companion to accompany them into the treatment area, to minimize the chances that they will feel coerced into silence by an abusive companion. If there is a concern for the patient's safety or a companion refuses to leave the patient in private, hospital security or police should be involved. A history of previous trauma, chronic complaints, psychological symptoms, or other red flags for IPV (inconsistent story, injury not consistent with chief complaint, multiple injuries in various stages of healing, partner who will not leave the patient's side) should be sought when obtaining the history. If there is a language barrier, an interpreter should be provided. It is inappropriate to use a family member as an interpreter when IPV is suspected.

Multiple approaches to universal, standard screening for IPV are available, and can be implemented via face-to-face screening, paper screening, or computerized screenings. The Partner Violence Screen is one option, which has been previously validated in healthcare settings (18). It is a simple, three-question screen for IPV that is easy and quick to administer. The screen is as follows:

1. Have you been hit, kicked, punched, or otherwise hurt by someone in the past year? If so, by whom?
2. Do you feel safe in your current relationship?

3. Is there a partner from a previous relationship who is making you feel unsafe now?

If a patient discloses IPV, the physician's first task is to assess the patient's safety. It is important to determine whether the patient has a safe place to stay and has a safety plan if she chooses to return home. Regardless of the severity of the presenting complaint or injury, the best indicator of danger is the patient's own assessment. The frequency and severity of previous attacks, as well as verbal threats of violence are also good guides to current risk. Presence of a weapon in the home, prior battering episodes, and partner substance use may increase risk of harm. Additionally, IPV victims are most likely to be killed when they are in the act of leaving or immediately after they have left their abuser. Enlisting the services of a social worker can help bring victims into contact with resources such as shelters, social services, legal assistance, support groups, and other referrals that may benefit the patient.

Providers should also document the ED visit thoroughly. A review of IPV patient ED charts found that site of assault was not documented in 88% of charts, force/object use was not documented in 13% of charts, and police involvement was documented in only 54% of cases in a state that mandates reporting of IPV (12). It is also important to document the patient's exact words, affect, and emotions, as factors can determine whether the patient's statement will be admissible as evidence in court. Additionally, photographs or body maps should be used to document injuries. An accurate and thoroughly documented medical record can be an asset to an IPV victim's case.

Violence in the ED

Many violent encounters in the ED can be prevented if a situation is recognized and controlled before an incident occurs. It is important to take steps to avoid confrontation, as patients often act out of a sense of fear or danger. Healthcare providers should never respond to patients' threats with threats of their own. All assaults against medical personnel should be reported to law enforcement agencies.

The patient should be approached from the side and should be watched for possible missiles or weapons. A nonoffensive posture, with hands out front but not raised, should be employed. The care provider should be cognizant of the patient's personal space and stay approximately two arm lengths away. It is important to acknowledge the patient's needs and ask him or her to discuss the problem. The patient should be informed in a low voice that help is available and that support will be provided but that the patient must take control of his or her own behavior. Expectations should be defined, and the consequences of aggressive behavior need to be clear. Frequently, talking to the patient and making offers of food and drinks may be calm and defuse the situation.

When possible, the patient should be interviewed alone and in private, but the provider should keep the door ajar and maintain space between the patient and the door should an escape be necessary. Some patients may not respond to these measures, and here a "show of force" may be needed. Before interviewing the patient, assemble a group of security personnel who will remain within calling distance. Frequently, this show of force may be sufficient to help disorganized patients gain control of their thoughts and behavior and back down.

The history may be difficult to obtain, and other sources, such as family members, friends, and medical records, should be used. A physical examination should be performed to exclude an organic cause of the patient's behavior (see Table 383.2). Blood tests, including toxicology screen and a blood sugar, should be obtained.

ED MANAGEMENT

Interpersonal Violence

If the police are not already involved, the physician can offer to call them or help the victim to do so. The patient should be told that battering is a crime and that he or she does not deserve to be treated in this manner. If a sexual assault occurred, state law often requires providers to report all rapes and sexual assaults. Cases involving the abuse or neglect of elders, minors, and certain persons

with disabilities must also be reported to the appropriate government agencies.

Some states may also require reporting of injuries from IPV. It is important to be familiar with the state laws that apply to reporting IPV, because these laws vary considerably.

If the patient chooses not to talk with police or social workers, it is important for the provider to be empathic and not to criticize the patient. Offer the patient information and contact numbers, which she may use later. Ensure that the patient is safe to go home and that he or she has a safety plan such as preparing an escape route should the situation at home escalate.

Violence in the ED

If a patient is or becomes combative or poses a danger to themselves or others, physical restraints may be needed. Explain clearly to the patient what is about to happen and why. Assemble a team, preferably with five members, four to restrain the limbs and one to act as team leader. Soft restraints should be used to secure each limb to the stretcher. After the patient is restrained, he or she should be searched for weapons or objects that could inflict harm and then moved to a quiet area. Zun (19) reported that the most common complications of physical restraints were vomiting, injuring self, and increasing the patient's agitation.

Pharmacologic intervention may be required if the patient remains agitated and uncooperative. Twenty-eight percent of patients in one study who were already physically restrained required chemical restraints (19). Frequently used agents include haloperidol (2 to 10 mg intramuscularly or intravenously in the young and 0.5 to 2.0 mg in the elderly) or benzodiazepines (e.g., diazepam 5 to 10 mg, or lorazepam 2 to 4 mg, intravenously or orally). Geodon (10 mg intramuscularly every 2 hours or 20 mg intramuscularly every 4 hours) has also been approved by the US Food and Drug Administration (FDA) for active psychosis. One randomized trial reported that haloperidol produced a faster onset of sedation and more clinical improvement over the first 2 hours

than did lorazepam, although there were no differences in the need for additional intervention or physical restraints between these medications (20). The reason for physical or chemical restraint use, as well as specific alternative measures implemented to avoid restraints and to ensure the patient's comfort and safety in restraints should be clearly documented in the medical record (19).

CRITICAL INTERVENTIONS

- Identify victims of violence.
- Develop a safety plan and involve authorities and local agencies with victims.
- Intervene early with potentially violent patients prior to escalation.

DISPOSITION

Victims of IPV should be asked where they will go if they leave the ED and who is waiting for them outside. If necessary, they can leave through a less-visible exit. All patients at risk for IPV should be given a list of emergency numbers and community resources. The option of overnight hospitalization should be discussed with the victim if he or she does not have a safe place to go upon discharge.

The discharge plan should include specific considerations for the patient's need including a safe place to stay and resources for daily living, including as money, personal documents, car keys, and clothing for herself and her children. IPV victims should be informed of local programs for battered women that provide free, confidential social and legal services as well as housing, child care, and practical support.

Physicians should discuss protection against sexually transmitted diseases and pregnancy, especially for those patients who have been raped or who have experienced coercive sexual activity as part of the violence.

For patients with violent behavior in the ED, some may be discharged after a period of observation in the ED (e.g., those with alcohol- or drug-induced violent behavior). Some may require

admission because of an underlying medical condition. Other patients may require further evaluation by mental health services and admission to psychiatric facilities. Patients without medical or psychiatric conditions requiring admission and who are under arrest may be discharged to the custody of law enforcement authorities after a medical evaluation.

Common Pitfalls

- Failure to make the diagnosis of IPV (especially in patients who may not disclose abuse, including elderly patients, patients with a language barrier, or patients who present to the ED with the perpetrator).
- Asking about IPV in the presence of a partner or family members.
- Failure to provide appropriate referrals and follow-up for victims of IPV.
- Failure to recognize the patient who is starting to escalate and who could have been calmed before the situation gets out of control.
- Attributing violent behavior to drug or alcohol intoxication without looking for an organic cause.
